short interval between plasma sampling and the onset of hypertension. A single preeclamptic patient (No. 5) had a normal early fibronectin level (300 μg/ml). However, the fibronectin level in this patient was elevated (440 μg/ml) at the time of diagnosis 45 days later, so a rise in the level before the onset of hypertension cannot be ruled out.

In none of the 23 control, uncomplicated pregnancies was an abnormal fibronectin level detected (Table II). The mean (±SD) fibronectin concentration for the control group was 271 ± 70 μg/ml. The difference between the groups was significant ($p < 0.001$).

Comment

These data suggest that the fibronectin rise in preeclampsia may occur before weight gain, abnormal edema, or hypertension becomes apparent. The relationship of the elevation of this glycoprotein to the pathophysiologic processes involved in preeclampsia is not apparent from our study; however, these results do suggest that the rise in fibronectin is not simply a consequence of vasospasm and hypertension characteristic of this disorder. The temporal relationship of the rise in fibronectin levels to the onset of symptoms would suggest that an endothelial cell abnormality may be the earliest pathologic process in these patients, occurring well before hypertension is evident.

Measurement of plasma fibronectin levels would appear to be a sensitive indicator not only for preeclampsia but for diagnosis of incipient preeclampsia in normotensive gravid women destined to become clinically preeclamptic later in pregnancy. Although a larger study is needed to verify the apparent sensitivity, specificity, and predictive value of fibronectin levels found in this small group of patients, these data suggest that further investigation of this glycoprotein might improve neonatal outcome by allowing earlier detection as well as provide insight into the pathophysiologic characteristics of the preeclamptic syndrome.

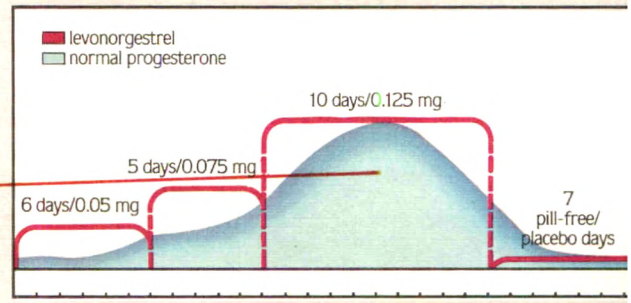
THE TEXTBOOK TRIPHASIC

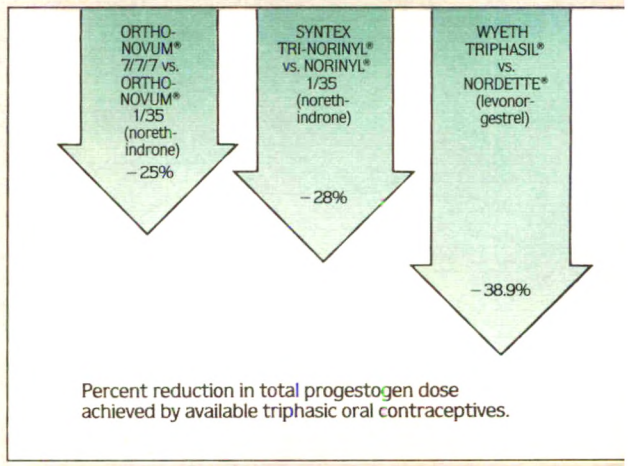
1986 EDITION



IT REDUCES DOSE... BUT NOT PERFORMANCE

TRIPHASIL® adjusts both estrogen and progestogen to follow a woman's normal hormonal patterns.

Estrogen—increased during periovulatory period



Estrogen is increased during the periovulatory period assure contraceptive efficacy. Progestogen is increas throughout the secretory period for added endometr support when it's most needed.

Progestogen—increased for added endometrial support

TRIPHASIL® offers the lowest total estrogen content any phasic regimen and the greatest reduction in pr gestogen—in fact, the lowest total hormonal dose of a combination oral contraceptive—without compromisi performance.

Lowest total dose of any combination O.C.

Percent reduction in total progestogen dose achieved by available triphasic oral contraceptives.

THE TEXTBOOK TRIPHASIC
1986 Edition

NEW STUDIES CORROBORATE INITIAL FINDINGS OF MINIMAL METABOLIC IMPACT

Numerous studies now support the conclusions of initial investigators—that low dose TRIPHASIL® can be expected to have minimal impact on lipid metabolism.

↑ Increased ↓ Decreased ⇌ No Significant Change □ Not Tested

INVESTIGATOR	(MONTHS)	TOTAL CHOLESTEROL	TRIGLYCERIDES	HDL CHOLESTEROL	LDL CHOLESTEROL
GASPARD[1]	6	⇌	⇌	⇌	⇌
VERMEULEN[2]	6	⇌	⇌	⇌	⇌
HARVENGT[3]	6	⇌	⇌	⇌	⇌
SKOUBY[4]	6	⇌	↑	⇌	⇌
MÄRZ[5]	3	⇌	↑	⇌	⇌
BRIGGS[6]	18	⇌	↑	⇌	
CULLBERG[7]	6	⇌	⇌	⇌	
SCHIJF[8]	6	⇌	⇌	⇌	
LARSSON-COHN[9]	6	⇌	↑	⇌	

No significant lipid impact up to 18 months of use

Throughout this extensive battery of studies,[1-9] the TRIPHASIL® formulation produced no significant change in total cholesterol, HDL cholesterol or LDL cholesterol. Some studies did not show a significant increase in triglycerides, while others did. TRIPHASIL® has also been shown to have no significant impact on carbohydrate metabolism[6] or blood pressure means.[10]

No significant impact on BP means or carbohydrate metabolism

A study in documented performance

See important information on last page.

LOW INCIDENCE OF BREAKTHROUGH BLEEDING ENCOURAGES PATIENT ACCEPTANCE

In clinical trials involving 35,036 cycles of TRIPHASIL® use,[10] patients experienced a high degree of contraceptive efficacy and an extremely low incidence of breakthrough bleeding.*

This resulted in an excellent record of patient acceptance. Only 0.6% of patients discontinued their TRIPHASIL® regimen because of breakthrough bleeding.

Only 0.6% dropouts due to BTB

PREFERRED PACKAGING

TRIPHASIL® offers easy-to-remember Day 1 start, with no need for back-up contraception during the first cycle when taken as directed.† The discreet, reusable compact —preferred by patients and physicians[11]—helps patient stay on schedule, month after month.

No need for back-up contraception in 1st cycle

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.

† No first-cycle pregnancies in 3,546 women using no additional protection. In worldwide postmarketing experience, only one first cycle pregnancy has been reported in the literature. (Graham H: Letter to Editor, *Br Med J 284*:422, 1982.) **For dosage and administration, see brief summary on last page.**

Only Triphasil® Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

Wyeth

21- and 28-day regimens

A study in documented performance

86, Wyeth Laboratories

IN BRIEF:
TRIPHASIL®—6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen)—Triphasic regimen.

Indications and Usage—TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possib types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing O Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increas spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended tha any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy i confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation o pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of bec pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clin recommend 3 months, although no precise information is available on which to base this. The administration progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significar percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observe on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three stu were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some wom hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalenc 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previous had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hype sion that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recur persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patie discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional cau should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequat diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while poten useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young w without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinu OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use ot methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularitie

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity a quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk o mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's unt has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should prescribed for longer than 1 year without another physical examination and Pap smear.

2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in s

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depr recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and us alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with ca monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disc migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be admin with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxin deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containin

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrin induced platelet aggregability.

c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measu protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, re the elevated TBG; free T4 concentration is unaltered.

d. Decreased pregnanediol excretion.

e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associate concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, p sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings section for information on carcinogenesis.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral he rhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an a ciation between the following conditions and use of OC's although additional confirmatory studies are needed mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. N and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of p during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. G intestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in n flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of tre edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; c weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactat given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (ste intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the a has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, cl appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema n erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's b young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—For maximum contraceptive effectiveness, Triphasil must be taken exactly as d and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of med or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptiv method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

Cardiovascular alterations in severe pregnancy-induced hypertension: Effects of intravenous nitroglycerin coupled with blood volume expansion

David B. Cotton, M.D., Stephen Longmire, M.D., Monica M. Jones, M.D., Karen F. Dorman, R.N., Joy Tessem, M.D., and Thomas H. Joyce III, M.D.

Houston, Texas

Control of blood pressure in severe pregnancy-induced hypertension has often relied on agents with an unpredictable onset and duration of action. Because intravenous nitroglycerin is a potent, rapidly acting agent with a hemodynamic half-life measured in minutes, we evaluated its cardiovascular effects with and without volume expansion in six patients with severe pregnancy-induced hypertension. Nitroglycerin alone reduced mean arterial pressure by 27.5% without any significant changes in heart rate, central venous pressure, or stroke volume. The pulmonary capillary wedge pressure fell from 9 ± 3 to 4 ± 2 mm Hg ($p < 0.05$) while the cardiac index decreased from 3.51 ± 0.67 to 2.87 ± 0.76 L/min · m^2. Oxygen delivery fell significantly ($p < 0.05$), from 617 ± 78 to 491 ± 106 ml/min · m^2. While volume expansion alone had no effect on mean arterial pressure, the combination of blood volume expansion and nitroglycerin resulted in a marked resistance to the hypotensive effect of nitroglycerin. Cardiac index, pulmonary capillary wedge pressure, and oxygen utilization were not significantly different from baseline values when volume expansion preceded nitroglycerin. We conclude that the ease with which nitroglycerin reduces blood pressure is dependent on the individual patient's volume status. Although volume expansion allows one to maintain cardiac index, pulmonary capillary wedge pressure, and oxygen utilization when used in combination with nitroglycerin, this benefit may be offset by a concomitant reduction in hypotensive capability. (Am J Obstet Gynecol 1986;154:1053-9.)

Key words: Pregnancy-induced hypertension, nitroglycerin

Pharmacologic control of blood pressure in severe pregnancy-induced hypertension has traditionally relied on the use of hydralazine. While hydralazine is appropriate in most situations, there are some occasions where another agent might be of benefit. One clear circumstance is the patient in whom hydralazine fails to control severe life-threatening hypertension.[1] Another problem area is the patient with severe pregnancy-induced hypertension undergoing cesarean section under general anesthesia. Hydralazine's slow onset of action does not make it an ideal agent for controlling the brief but severe episode of hypertension seen with tracheal intubation.[2] Furthermore, prolonged hypotension secondary to hydralazine in the face of excessive surgical blood loss could compound an already difficult clinical situation.

A less clear but equally important circumstance is the patient with borderline placental function where relatively uncontrolled decrements in blood pressure could adversely affect the fetus.[3, 4] The unpredictability of hydralazine's onset of action as well as duration of action lends itself to this potentially dangerous situation.[5-10]

Intravenous nitroglycerin is a potent, rapidly acting antihypertensive agent with a hemodynamic half-life measured in minutes.[11-13] Although nitroglycerin is thought of primarily as a venodilator, it also induces arterial hypotension.[14-16] These properties make nitroglycerin a candidate for control of the arterial hypertension seen in pregnancy. Because of nitroglycerin's rapid onset as well as ease of regulation, we initiated a prospective study of intravenous nitroglycerin's hemodynamic effects when used for control of blood pressure in severe pregnancy-induced hypertension. In this study we also analyzed the hemodynamic effects of blood volume expansion when used in conjunction with intravenous nitroglycerin.

Methods

Patient population. Six patients with severe pregnancy-induced hypertension, as manifested by a diastolic blood pressure ≥110 mm Hg made up the study group. The mean maternal age was 20.4 ± 2.9 years and the average gestational age was 37.3 ± 3.6 weeks. This study was approved by the Institutional Review

From the Departments of Obstetrics and Gynecology and Anesthesiology, Baylor College of Medicine.

Received for publication October 16, 1985; revised December 30, 1985; accepted January 8, 1986.

Board for Human Utilization at Baylor College of Medicine.

Hemodynamic measurements. After written informed consent was obtained, percutaneous catheterization of the right side of the heart with a triple lumen, flow-directed pulmonary artery catheter (Swan-Ganz, Edwards Laboratories) and arterial cannulation of the radial artery were performed. The position of the catheter was documented by pressure waveforms and confirmed by a single chest x-ray film.

All measurements were made with the zero reference level at the midaxillary line with the patient supine and a wedge under the right hip. All patients were receiving a continuous intravenous magnesium sulfate infusion of 1.5 to 2.5 gm/hr for at least 1 hour before any measurements were obtained in order to obviate any effects of magnesium sulfate.[17] The following hemodynamic variables were measured: (1) heart rate, (2) mean arterial pressure, (3) central venous pressure, (4) mean pulmonary arterial pressure, (5) pulmonary capillary wedge pressure, and (6) cardiac output. Systemic and pulmonary arterial pressures were determined by waveform analysis with the use of an eight-channel recording system (Hewlett-Packard). Heart rates were derived from an electronic cardiotachometer. Cardiac outputs were determined by a bedside thermodilution cardiac output computer (Hewlett-Packard) with the use of 0° C iced injectate. Five cardiac outputs were performed at each measurement interval. The high and low cardiac output values were discarded and the mean of the remaining three values was recorded. Arterial and mixed venous blood gas samples were obtained anaerobically at the time of each cardiac output determination and analyzed for pH and blood gases

Table II. Comparison of the effects of nitroglycerin, with and without volume expansion, on cardiac index, stroke volume index, left ventricular stroke work index, and systemic vascular resistance

via an Instrumentation Laboratory 1301 pH/blood gas analyzer. Hemoglobin oxygen saturation and total hemoglobin were measured directly with the use of an Instrumentation Laboratory 282 Co-oximeter System.

Derived variables included cardiac index, stroke volume index, systemic vascular resistance index, and left ventricular stroke work index. All variables were indexed according to the patient's height and weight with the use of a nomogram derived from nonpregnant patients. The body surface has not been determined in pregnant patients, but for comparative reasons standardization was considered necessary. Derived oxygen-related variables measured included the oxygen delivery index and the oxygen consumption index. Standard formulas were used to calculate all derived variables.[18] Analysis of data was by Duncan's multiple comparison technique with the use of the Statistical Package for the Social Sciences; significant levels were taken as $p < 0.05$. Data are shown as the mean ± SD.

Nitroglycerin administration. After a period of at least 1 hour of stabilization, baseline hemodynamic parameters were obtained and intravenous nitroglycerin was initiated at 0.1 μg/kg/min. The nitroglycerin dose was titrated until either maternal or fetal symptoms contraindicated further reduction or a mean arterial pressure of 106 mm Hg was reached. A second set of hemodynamic measurements was then obtained. After the second set of hemodynamics the nitroglycerin infusion was discontinued and each patient underwent volume expansion to at least a pulmonary capillary wedge pressure of 10 mm Hg with either 5% or 25% albumin. Hemodynamic measurements were recorded after volume expansion and then a final set of measurements was obtained after reinstitution of nitroglycerin.

Results

Hemodynamic effects of nitroglycerin. The effects of intravenous nitroglycerin alone, blood volume expansion alone, and nitroglycerin in combination with volume expansion on heart rate, mean arterial pressure, central venous pressure, mean pulmonary arterial pressure, and pulmonary capillary wedge pressure are shown in Table I. It can be seen that nitroglycerin significantly ($p < 0.05$) reduced mean arterial pressure by 27.5% while the mean pulmonary arterial pressure and

‡$p < 0.05$ versus volume expansion plus nitroglycerin.
§$p < 0.05$ versus nitroglycerin.

pulmonary capillary wedge pressure were reduced by 28.6% and 55.6%, respectively. This occurred without any significant changes in heart rate or central venous pressure. The dose of nitroglycerin required to satisfactorily reduce mean arterial pressure was 1.2 ± 0.53 μg/kg/min. In Table II the hemodynamic changes induced by nitroglycerin on cardiac index, stroke volume index, left ventricular stroke work index, and systemic vascular resistance index are shown. Cardiac index and stroke volume index decreased 18.2% and 23.6%, respectively, while the left ventricular stroke work index declined 41.1%. A falling trend in systemic vascular resistance was noted after intravenous nitroglycerin but because of the wide standard deviation this trend was not significant. The lack of change in systemic vascular resistance index was also attributable to the fact that cardiac index fell concurrent with the reduction in mean arterial pressure.

Oxygen-related parameters are detailed in Table III. The oxygen delivery index fell significantly ($p < 0.05$) from 617 ± 78 to 491 ± 106 ml/min · m^2 of body surface area while oxygen consumption decreased from 123 ± 30 to 111 ± 30 ml/min · m^2 (9.8%, NS).

Effects of volume expansion. After the reduction of blood pressure with nitroglycerin alone, the effects of blood volume expansion with either 5% or 25% albumin were studied. Each patient received either 250 ml aliquots of 5% albumin or 50 ml aliquots of 25% albumin every 30 to 40 minutes until the pulmonary capillary wedge pressure was at least 10 mm Hg. The volume of 5% albumin required for four patients was 250, 500, 1250, and 1250 ml, respectively. The dose of 25% albumin was 125 ml in one patient and 100 ml in the other. Intravenous nitroglycerin was then reinstituted with the goal of reducing mean arterial pressure to 106 mm Hg. The effects of blood volume expansion alone are shown in Table I. Volume expansion resulted in significant ($p < 0.05$) increases over baseline values in both pulmonary capillary wedge pressure and cardiac index accompanied by a 23.2% decline in systemic vascular resistance. There was, however, no appreciable effect on mean arterial pressure. Volume expansion increased oxygen delivery from 617 ± 78 to 741 ± 129 ml/min · m^2 ($p < 0.05$). Oxygen consumption did not significantly increase after volume expansion (value before volume expansion was 123 ± 30 ml/min · m^2 and that after volume expansion was 128 ± 29 ml/min · m^2).

Effects of volume expansion and nitroglycerin. In Table I the cardiovascular effects of nitroglycerin with and without blood volume expansion are compared. There was a significantly higher mean arterial pressure after volume expansion. This was due to an inability to lower mean arterial pressure to the range of 106 mm Hg. This level could not be reached even though doses as high as 35 μg/kg/min were given. The pulmonary capillary wedge pressure and cardiac index after nitroglycerin in combination with volume expansion remained significantly ($p < 0.05$) elevated over those values seen with nitroglycerin alone. These indices were not significantly different from baseline values obtained before initiation of any therapy.

The combination of nitroglycerin and volume expansion resulted in an oxygen delivery value of 614 ± 56 ml/min · m^2. This was significantly greater than the 491 ± 106 ml/min · m^2 seen with nitroglycerin alone ($p < 0.05$). Oxygen consumption was 135 ± 22 ml/min · m^2 with combination therapy and 111 ± 30

ml/min · m² with nitroglycerin alone (NS). Although there was a 22% increase in oxygen consumption when combination therapy was compared to nitroglycerin alone this was not statistically significant. Furthermore, combination therapy did not significantly improve oxygen consumption over baseline values obtained before any therapeutic intervention (123 ± 30 ml/min · m²).

Fetal and neonatal outcome. The use of nitroglycerin in these six patients did result in two areas of concern. First, in two patients when nitroglycerin was initiated without volume expansion, the mean arterial pressure was inadvertently and suddenly lowered to <106 mm Hg. Concomitant with the reduction in blood pressure below 106 mm Hg, fetal heart rate abnormalities including late decelerations and bradycardia occurred. In the first patient the mean arterial pressure decreased to 61 mm Hg and returned to 93 mm Hg 13 minutes after discontinuation of the nitroglycerin infusion. Late decelerations began 13 minutes after discontinuation of the nitroglycerin infusion and resolved after 10 minutes. In the second patient, the mean arterial pressure decreased to 76 mm Hg and returned to a mean of 119 mm Hg 1 minute after discontinuation of the nitroglycerin infusion. The fetal heart rate decreased to 75 bpm during the hypotensive episode and returned to 120 bpm 8 minutes after discontinuation of the nitroglycerin infusion. In each case the infusion was restarted at a lower dosing regimen and the ominous fetal heart rate changes did not recur.

The second area of concern was the development of a very flat fetal heart rate tracing with an average beat-to-beat variability of <5 bpm. This occurred in three patients. Because of the absence of any other fetal heart rate changes, labor was allowed to continue. At delivery, umbilical cord gas values were obtained in four of the six infants. These revealed a mean pH of 7.26 ± 0.05 units in the umbilical artery and 7.32 ± 0.03 units in the umbilical vein. The mean Apgar scores for the group at 1 and 5 minutes were 6.8 ± 2.1 and 8.7 ± 0.7, respectively. Five of the six infants had no complications in the nursery and were discharged home with the mother. One infant (the only infant weighing <2300 gm) weighed 820 gm and that infant's hospital course was complicated by respiratory distress syndrome and by intermittent apnea and bradycardia, and prolonged nutritional support was required.

Comment

This study demonstrates that the major cardiovascular effect of intravenous nitroglycerin in patients with severe pregnancy-induced hypertension is effective reduction of the mean arterial pressure as well as the pulmonary capillary wedge pressure and cardiac index. It is of interest that a rapid decline in pulmonary capillary wedge pressure often preceded the expected drop in mean arterial pressure. This observed fall in pulmonary capillary wedge pressure was used as a clinical predictor that the nitroglycerin infusion dose was near the level required to produce hypotension. No significant changes occurred in heart rate, central venous pressure, or stroke volume after nitroglycerin. The decline in cardiac index was also accompanied by a fall in oxygen delivery and consumption. Although we did not evaluate uteroplacental blood flow in this study, the fall in oxygen utilization could conceivably be secondary to this system.

Previous studies in nonpregnant patients have also shown a similar fall in pulmonary capillary wedge pressure with intravenous nitroglycerin.[19-31] The lack of significant changes in heart rate seen in this study is consistent with previous studies of intravenous nitroglycerin.[19, 20, 23-25, 27, 30-33] Other studies have documented either a decrease[22, 26, 29] or an increase[21, 28] in heart rate with nitroglycerin.

A comparison of nitroglycerin's effect on cardiac output with previous studies is difficult as myocardial compromise is almost always present in studies of nonpregnant patients. However, our results are consistent with previous observations that patients with low or normal filling pressures respond to nitroglycerin by a decrease in stroke volume or cardiac output while patients in left ventricular failure cardiac output either maintain or improve cardiac output despite a fall in left ventricular filling pressure.[33, 34] Also Christensson et al.,[19] in a study of intravenous nitroglycerin in normal nonpregnant patients, found a small decrease in cardiac output when patients remained in the supine position and blood pressure remained stable. When continuous breathing against positive pressure was initiated, they documented a 30% fall in stroke volume and cardiac output. The downward trend in cardiac index seen before volume expansion with nitroglycerin was clearly offset after volume expansion. This is consistent with previous studies of nitroglycerin showing an improvement in cardiac output when decreased filling pressures were restored by volume expanders.[35, 36]

The effects of volume expansion alone were an increase in cardiac index and pulmonary capillary wedge pressure without any change in mean arterial pressure. This is not in agreement with previous studies in which volume expansion has resulted in a lowering of blood pressure in severe pregnancy-induced hypertension.[37, 38] We feel that this lack of effect on blood pressure may be attributable to a more severe degree of hypertension in our study population. Additionally, the increase in cardiac output most likely offset any reduction in compensatory vasoconstriction seen because of hypovolemia.

The combination of nitroglycerin and volume expansion allowed a reduction in mean arterial pressure

while cardiac index and oxygen utilization were maintained in the range seen before therapy. However, there was no increase in these parameters compared with pretherapy values and volume expansion prevented lowering of the mean arterial pressure to levels obtained with nitroglycerin alone. This resistance to intravenous nitroglycerin was seen despite a greater than tenfold increase in the dose of nitroglycerin.

The occurrence of diminished fetal heart rate variability in three of the five patients in this study is of interest. A possible explanation is the observation that a loss of cerebral autoregulation and increased intracranial pressure occur in cats[39] as well as humans[40-42] after nitroglycerin. This may be due to increased capacitance vessel dilatation and increased cerebral volume. Although there appeared to be no adverse effects on fetal acid-base status in this study, the documentation of a decrease in oxygen delivery when nitroglycerin was instituted in a non–volume-expanded state is worrisome. Further investigation with an expanded patient population and neurobehavioral testing of the neonate appear necessary before nitroglycerin is recommended under less than life-threatening circumstances.

In summary, intravenous nitroglycerin is an efficacious agent for the reduction of blood pressure in the pregnancy complicated by hypertension. It appears that the ease with which blood pressure can be reduced is dependent on the volume status of the individual patient. In patients with a relatively low pulmonary capillary wedge pressure an easily obtainable decline in mean arterial pressure can be achieved. This fall in mean arterial pressure is also accompanied by a fall in cardiac index and oxygen utilization. The combination of blood volume expansion and nitroglycerin does allow cardiac index and oxygen utilization to be maintained at higher levels than those seen when volume expansion is not used. However, this benefit may be offset by a concomitant reduction in nitroglycerin's hypotensive capability. Finally, a decrease in fetal heart rate variabilty does occur in some patients after institution of nitroglycerin. Further work with an expanded study population is needed to establish whether this occurrence adversely affects neonatal outcome.

A retrospective study on the effects of steroid administration and prolongation of the latent phase in patients with preterm premature rupture of the membranes

Fernando Arias, M.D., Ph.D., Alfred B. Knight, M.D., and Paul B. Tomich, M.D.

St. Louis, Missouri

To address the issues of whether corticosteroid treatment and prolongation of the latent phase improve the outcome of pregnancy in patients with preterm premature rupture of the membranes, we studied 96 patients with premature rupture of the membranes who were delivered of infants of adequate weight for gestational age with birth weights between 751 and 2000 gm and who had a latent period longer than 48 hours. Of these 96 infants, 53 received treatment with steroids and tocolytic agents and 43 received no treatment. We found a significant decrease in perinatal mortality and in the incidence of moderate and severe hyaline membrane disease in infants whose mothers received glucocorticoids. The protective effect of glucocorticoid therapy was limited to infants with a birth weight between 751 and 1000 gm or with a gestational age of 27 to 28 weeks. We also found a significant increase in perinatal mortality, mainly due to infection, when the latent phase was prolonged for >7 days, regardless of the type of management. (AM J OBSTET GYNECOL 1986;154:1059-63.)

Key words: Fetal membranes, premature rupture, corticosteroids, hyaline membrane disease

There are several controversial areas in the management of patients with preterm premature rupture of the membranes. Significant discrepancies in opinion involve the maternal and fetal advantages and disadvantages of prolongation of the latent period and the use of glucocorticoids to stimulate fetal lung maturation. This controversy has resulted in different approaches to the management of these patients and led us to study retrospectively the outcome of patients with preterm premature rupture of the membranes man-

aged with or without steroid administration. We attempted to determine whether significant maternal or fetal risks were associated with prolongation of the latent period and if maternal glucocorticoid therapy offered significant advantages in the management of the problem.

Material and methods

We collected information about the outcome of pregnancy in 439 patients (approximately 4% of all the obstetric admissions to the hospital during the study period) who had an admitting diagnosis of preterm premature rupture of the membranes. The diagnosis of ruptured membranes was accepted if there was documentation of appropriate color changes in Nitrazine paper and the presence of ferning on microscopic examination of the dried vaginal fluid obtained by a sterile speculum examination. The diagnosis of ruptured membranes was confirmed by a real-time ultrasound demonstration of reduced or absent amniotic fluid in the uterine cavity.

At the time of the data review, we excluded from analysis all patients who were delivered of babies with birth weights >2000 gm or with a gestational age longer than 34 weeks. Also excluded were all patients delivered of babies with birth weights <751 gm or with a gestational age shorter than 26 weeks, all infants who were products of twin gestation and who remained in an intact amniotic sac, and all infants classified as small for gestational age by the pediatrician. Patients with diabetes, chronic hypertension, or preeclampsia complicating their pregnancies were excluded, as were patients with a latent phase (interval between time of rupture and time of delivery) of <48 hours. We also excluded all patients who received incomplete treatment with glucocorticoids and those who did not receive corticosteroids but were treated with labor-inhibiting drugs. Also excluded were patients with a positive shake test or phosphatidylglycerol determinations in amniotic fluid specimens collected from vaginal pools.

After all exclusions, 96 patients remained: 43 received no treatment, and 53 were treated with glucocorticoids and β-sympathomimetics (betamethasone, 12 mg intramuscularly, in two consecutive doses 24 hours apart, and terbutaline, 2.5 mg orally, every 4 to 6 hours for a minimum of 72 hours). These 96 patients were delivered of their infants when labor occurred, when chorioamnionitis was diagnosed or suspected, and when there was evidence of fetal distress. Obstetric indications determined the route of delivery. All babies in breech presentation were delivered by cesarean section. Prophylactic antibiotics were given, after cord clamping, to patients who were delivered by cesarean section and after vaginal delivery to patients with obvious signs and symptoms of chorioamnionitis.

At delivery the newborn infants were examined by the pediatricians, had surface cultures done, and were transferred to the appropriate nursery. Cultures were obtained from multiple sites in all neonates. The diagnosis of neonatal sepsis was reached if there was a positive culture from blood, urine, or cerebrospinal fluid. The gestational age was assigned after physical and neurological examination according to the method of Dubowitz et al.[1] The Apgar scores were assigned by the pediatrician attending the delivery.

Chorioamnionitis was a presumed diagnosis based on fetal or maternal tachycardia, elevated maternal leukocyte count with a shift to immature forms, elevated maternal temperature (≥100.6° F), or foul-smelling vaginal discharge. A positive amniotic fluid or cervical culture was not required for this diagnosis. The diagnosis of endometritis was a clinical diagnosis based on the findings of fever, a boggy and tender uterus on abdominal examination, and foul-smelling lochia, regardless of the results of the cervical or endometrial cultures. Febrile morbidity was defined as a temperature of ≥99.5° F on at least two occasions at least 24 hours apart.

The diagnosis of hyaline membrane disease was made if there were clinical symptoms (tachypnea, hypoxia) and typical findings on chest X-ray examination. For the purpose of this review, hyaline membrane disease was classified as mild (no need for positive-pressure ventilation; oxygen for up to 24 hours), moderate (positive-pressure ventilation for <24 hours; oxygen for >24 hours), and severe (positive-pressure ventilation and oxygen for >24 hours). Transient tachypnea of the newborn and neonatal pneumonia were separated from hyaline membrane disease. Intraventricular

hemorrhage was diagnosed by computerized tomographic scanning or by ultrasound examination. Intraventricular hemorrhage was classified as grade I to III according to Volpe.[2] Neonatal morbidity and mortality were assessed and recorded up to the time that the infants were discharged from the hospital.

The analysis of the data was carried out by means of two-tailed *t* test and Fischer exact probability test. All computations were made with the SAS version 5 statistical software.

Results

Characteristics of the patients. Given the retrospective nature of this study, it was surprising not to find significant differences between treated and untreated patients in terms of racial composition, number of primiparous patients, and duration of the latent period before admission. Similarly, no significant differences were found with respect to gestational age, birth weight, sex, and number of infants with low Apgar score at birth (Table I).

Maternal outcome. Maternal outcome was similar for the two groups of patients, and the incidence of cesarean section deliveries, chorioamnionitis, endometritis, and febrile morbidity was not significantly different between treated and untreated patients.

Fetal outcome. There was a significant difference in perinatal mortality between treated and untreated patients. In fact, there were six deaths among the 53 patients treated with steroids as compared with 12 deaths in the 43 patients who did not receive steroids ($p < 0.01$). Table II shows that the decrease in perinatal mortality observed among steroid-treated patients was significant only in babies with birth weights between 751 and 1000 gm. Table III shows that the perinatal mortality in both steroid-treated and untreated patients increased with prolongation of the latent phase. Table III also shows that the protective effect of steroid treatment was statistically significant only for patients with a latent phase >2 but <3 days in duration.

Table IV shows the incidence of culture-proved sepsis in steroid-treated and untreated neonates in relation to the length of the latent phase. Neonatal sepsis increased with prolongation of the latent phase for >7 days. In fact, sepsis was responsible for seven of 11 (63.6%) perinatal deaths occurring in patients who remained undelivered for more than 7 days after premature rupture of the membranes. The most frequently isolated pathogens in patients with neonatal sepsis were group B β-hemolytic streptococcus (four cases) and *Escherichia coli* (three cases).

Table V shows that the incidence of moderate and severe hyaline membrane disease was significantly less in steroid-treated patients than in untreated patients both in general and for infants with a birth weight between 751 and 1500 gm.

Comment

The combination of ruptured membranes and preterm gestation is a major cause of perinatal morbidity and mortality because of the high incidence of hyaline membrane disease, intraventricular bleeding, and neonatal sepsis. There is considerable controversy in the literature about the effect of prolonging the latent phase on the incidence of hyaline membrane disease. A recent excellent review[3] found 11 articles showing no difference in hyaline membrane disease with prolongation of the latent phase and 14 showing a decreased incidence. Although it is generally accepted that maternal treatment with corticosteroids reduces

the incidence of hyaline membrane disease in preterm gestations with intact membranes,[4] the effectiveness of this treatment in reducing the incidence or severity of hyaline membrane disease in patients with preterm premature rupture of the membranes is also controversial. Of nine articles in the recent literature that addressed this issue, four[5-8] suggest a positive effect and six[9-14] do not. In perhaps the best-designed study, Garite et al.[12] managed a group of 80 patients treated with glucocorticoids and compared their outcome with that of a similar number of untreated control patients and found no significant difference in the incidence of respiratory distress syndrome at different gestational ages. Among their least mature neonates (28 to 30 weeks), treated infants had a 25% incidence of respiratory distress syndrome compared with 48% in their control patients. Because of the small number of infants in this gestational age category, no statistical significance was established. They concluded that corticosteroids were not beneficial in patients with premature rupture of the membranes and recommended against their use. However, their two treatment regimens were not completely comparable because the steroid-treated patients were actively delivered after 48 hours and the untreated patients awaited delivery for obstetric reasons. Another prospective comparison[13] reached a similar conclusion but the duration of the latent phase in their steroid-treated and expectantly managed patients was significantly different (39.5 ± 12.8 hours in the steroid-treated group versus 94.6 ± 12.9 hours in the expectant management group).

A recent retrospective review[14] also denies the beneficial effects of glucocorticoid treatment in patients with preterm premature rupture of the membranes. However, although not stated in the article, the two treatment groups seem to be significantly different with respect to the duration of the latent phase (122.8 ± 237.8 hours in the control group versus 55.2 ± 13.7 hours in the glucocorticoid group) because steroid-treated patients were "timely" delivered.

In this study we found that management of patients with preterm premature rupture of the membranes including glucocorticoid administration, tocolysis with terbutaline, and prolongation of the latent phase was more advantageous than prolongation of the latent phase alone. The advantages were a decreased perinatal mortality and a decreased incidence of moderate and severe hyaline membrane disease. The beneficial effects of steroid and tocolysis administration were limited to pregnancies with babies between 751 and 1000 gm and with latent phases lasting >2 but <7 days. However, the value of these findings is limited by the retrospective nature of the study and the lack of adequate randomization of patients between treated and untreated groups.

Our results contradict the observations of Garite et al.,[12] Nelson et al.,[13] and Iams and Barrows.[14] We believe that the different results can be explained by the duration of the latent phase in steroid-treated and untreated patients, which is similar in the present study but was different in the work of Nelson et al.[13] and Iams and Burrows.[14] Also the duration of the latent phase in patients receiving steroids in this work (5.97 ± 5.5 days) seems to be significantly greater than in the patients of Garite et al.[12] (2.73 ± 1.7 days) because their treated patients were actively delivered after 48 hours while ours waited for the spontaneous onset of labor. Also all of our steroid-treated patients and none of the

untreated patients received terbutaline. β-Adrenergic agents may have an effect on fetal lung maturity and help to prevent the development of hyaline membrane disease,[15] and this is an additional factor that may partially account for the differences between our results and those of other studies.

The lack of timed delivery in the management of our patients made it possible to compare the neonatal outcome of some steroid-treated and untreated patients who remained undelivered >7 days after ruptured membranes. Our findings in this subgroup of patients suggest that the advantages of prolongation of pregnancy and treatment with steroids and tocolytic agents are lost after a latent phase of ≥7 days because of the increased incidence and severity of neonatal sepsis. This is an observation that, if supported by prospective studies, may indicate the need to deliver patients with preterm premature rupture of the membranes when they are close to a latent phase of 7 days.

In summary, the data collected in this study support the hypothesis that seroids, tocolysis, and prolongation of the latent phase are beneficial to patients with preterm premature rupture of the membranes when the birth weight is between 751 and 1000 gm or the gestational age is 27 to 28 weeks. The controversy in this area, however, has not concluded, and prospective studies using protocols whereby treated and untreated patients have a similar length of the latent phase are necessary and urgent.

Reported sexual assault in Nashville–Davidson County, Tennessee, 1980 to 1982

Peter S. Cartwright, M.D., and the Sexual Assault Study Group
Nashville, Tennessee

A review of the experience of 440 women reporting they had been raped was made from their initial contact with the police, through their medical-forensic examination at the county hospital emergency room, by any judicial proceedings, and by their longer term psychological counseling. The data were then compared with those from other municipalities. The assailant's use of a weapon seemed the strongest variable correlated with the victim's decision to press for prosecution. Being raped by a stranger or being physically injured did not correlate with this decision. Women most likely to have been victims of a previous rape were over 40 years old, were black, were assaulted by someone well known to them, or had some sort of mental health problem, and these variables were independent of each other. This implies these victims somehow suffer from an increased vulnerability to repeated rape. The data suggest that use of a county hospital emergency room for the medical management of rape victims discourages their reporting the event to the authorities and their seeking medical treatment. (Am J Obstet Gynecol 1986;154:1064-8.)

Key words: Reported sexual assault, sexual abuse, rape

The sexual abuse of women and children is an ancient problem, yet recently there has been an increase of the public's awareness of this issue. Several reports have appeared on the experiences of various municipalities concerning this problem.[1-5] This report provides this information for Nashville, Tennessee, and provides analysis of the many variables involved.

During the period of this study, the Metropolitan Nashville General Hospital served Davidson County in providing organized emergency health care to victims of sexual assault. The police brought all victims to the emergency room for examination and treatment. Individuals who arrived at the emergency room to first report the incident were given medical treatment and encouraged to report the episode to the police. Other health workers were involved with more long-term mental health issues. The experience then at the hospital was that for the entire county regarding emergency care for victims reporting a recent sexual assault. The unreported activities of private doctors and the unreported experiences of victims are unknown.

When an adult victim arrived in the emergency room, she was examined by a gynecology house officer who treated any injuries, collected documentation and forensic specimens using a standard rape evaluation form and rape kit, and provided prophylaxis against venereal disease and pregnancy. The Victim Intervention Program of the Metropolitan Police Department provided trained crisis intervention personnel to aid the victim during the immediate crisis and to act as a witness advocate during any court proceedings. Mental health situations requiring intense psychiatric intervention were identified by these personnel and referrals were made.

Cases involving children tended to be more chronic in nature and were usually managed through the pediatric clinic. These cases are not included in this study. Acute pediatric cases in which the child was seen in the emergency room are included but represent only a small fraction of the reported child sexual abuse cases.

When an arrest was made, the prosecution of the suspect was managed by a special division of the District Attorney's office. The forensic specimens were processed by the Tennessee Bureau of Investigation (TBI).

Material and methods

From July, 1980, through June, 1982, each patient seen in the Metropolitan Nashville General Hospital who reported having been sexually assaulted was included in this retrospective study. Data were collected from a review of the hospital record and then, for each patient, from personnel interviews and/or file reviews from the police department, the District Attorney's office, and the TBI. Cases involving arrest and trial without the victim visiting the emergency room and rape-homicide cases are not included.

Individual members of the Sexual Assault Study Group and their positions or affiliations are listed at the end of the article.

Received for publication October 8, 1985; accepted January 27, 1986.

Demographic data for the victim came from all available sources. When interviewed, the victim was asked if she had ever been raped before; a positive response was not broken down into childhood sexual abuse or a similar adult assault.

A wet preparation taken from the posterior fornix and a permanent stained slide of similar material was immediately examined by the gynecologist. The presence of motile-nonmotile sperm was recorded. The permanent slide was also examined by the TBI. A positive smear was one with whole or fragmented sperm recorded by either the gynecologist or the TBI. Vaginal and salivary specimens were collected and assessed for the presence of vaginal acid phosphatase and the secretory antigens of the ABO system.

Some of our tables present data as "adjusted frequency percent." This means that for each variable patients with missing data were excluded from the analysis, and the percent is of the total number with valid data. The number of valid cases for each variable is presented along with the adjusted frequency percent. Data were evaluated by means of cross-tabulations and logistic regression. Tests of significance by χ^2 were not appropriate since the data base represented the totality of the population studied and conclusions were not based on analysis of a representative sample.

Results

During the study, 500 people were seen who reported having been sexually assaulted. Of these, 17 were male, all of whom were either children or incarcerated or mentally retarded adults. Five women refused examination and 26 (5%) left against advice before being seen by a physician. There were 12 cases (2%) where the circumstances were such that the report was deemed unfounded by the police and the medical examination not requested. A total then of 440 women of all ages are included in this study. Not all victims were sure if vaginal, oral, or anal penetration had occurred. Twenty-eight thought that it had not, and thus the attack would seem not to meet the legal definition of rape, which requires that some sort of penetration (carnal knowledge) occur. While none of these 28 women had sperm in the vagina, three had objective evidence of vulvar trauma.

Table I presents demographic data for the victims. Overall, 49% of the victims said the assailant was a total stranger, while 20% said he was well known to them as an ex-husband-boyfriend, employer, neighbor, or relative. For 31%, he was known to her more casually as a friend of a friend, previous superficial acquaintance, or someone recently met at a party, bar, or the like. Victims less than 10 years old tended to know their assailants well. Black victims 21 to 30 years old were less likely to be raped by a total stranger than white victims of the same age (47% versus 69%). Victims at both extremes of age were likely to be assaulted in their own homes.

Table I. Demographic data for victims

	Adjusted frequency %
Age (yr) (n = 439)	
<10	6.8

Adjusted frequency is the percent of the total group with valid data for that variable (see text).

*Prepubertal, postmenopausal, hysterectomy, partner with vasectomy.

†Diagnosed psychiatric disorders, alcoholism, substance abuse, mental retardation.

About one in every five victims reported that she had been sexually assaulted before. Of the recurrent assault victims aged ≥16, 23% were assaulted by someone well known to them, while only 1% of first-time victims knew their assailant well. Victims aged ≥16 knew their assailant well 13% of the time and 28% of these had been previous victims of sexual assault. Of those assaulted by a stranger, only 12% had been previous victims.

The rates per capita were similar for both races in that younger women seem more likely to be the victims of rape. Black subjects, however, showed a persistently higher per capita rate than white subjects for all ages (Table II).

For victims 16 years of age or older, almost 50% were single, and 51% were vulnerable to pregnancy on the basis of the type of contraception used for voluntary coitus. This did not take into account the victim's menstrual phase or whether sperm were found in the va-

Table II. Reported rapes of women by age and by race-specific rates per thousand per year, 1980 to 1982

Age (yr)	*Black*	*White*
10-15	2.9 (15)	1.7 (20)
16-20	3.65 (22)	2.65 (37)

Over 51	0.15 (2)	0.1 (5)

Absolute numbers of victims are enclosed in parentheses. Children <10 years old were excluded.

gina. Pregnancy prophylaxis was discussed with all victims, but when all things were taken into consideration prophylaxis was given to only 10 patients. There were two victims in the study who probably did become pregnant as a result of the rape, and both had refused pregnancy prophylaxis.

Assault frequencies were independent of the season of the year, but 72% of the attacks occurred between 6:00 PM and 6:00 AM. Table III presents demographic data concerning the assault event itself. Those occurring at the assailant's home usually involved an acquaintance and the victim voluntarily accompanied the assailant to his home. Victims 16 to 30 years old were assaulted less frequently in their own home or their assailant's home. There was one assailant in 84% of the cases, two assailants in 10%, and more than two in 6%.

A weapon, most commonly the handgun, was involved in 39% of the cases. Weapon use was not related to the time of day or year or to the race of the victim. Weapons were rarely involved when the victim was less than 15 years old. Victims aged 21 to 30 had weapons used against them more often (52%) than those aged 16 to 20 (35%) or over 31 (45%). The age of the victim, however, did not correlate with which type of weapon was used. Assaults involving a knife or club were associated with about twice the rate of nongenital victim injury as cases involving a gun (61% and 79% versus 34%).

Victim injury was not more likely if multiple assailants were involved. Most physical injuries consisted of abrasions, scratches, or bruises that required little or no treatment. Genital injuries were those apparent without the use of special magnification or staining. Five patients were hospitalized because of physical injury; four of these were for neurosurgical indications, and in one patient a posterior vaginal fornix laceration required operative repair.

Forced penile penetration was reported to have occurred by 384 of the victims: 63% vaginally only, 2% orally only, 1% anally only; the remainder involved a combination of these. Before coming to the hospital 6% of the victims douched, 20% took a bath, and 26% changed their clothing. One third of the victims arrived at the hospital within 1 hour of the assault and 81% within 4 hours.

Table III. Demographic data for the assault event, given in adjusted frequency percent

	Adjusted frequency %
Location of assault (n = 418)

6-12	12.5
13-24	1.5
>24	0.2

*Public park, field, vacant lot or building.

Venereal disease prophylaxis was discussed with all patients and given to 86%. Endocervical cultures were positive for *Neisseria gonorrhoeae* in 6.5%. Of the rectal cultures taken, 6.7% were positive, as were 2% of the pharyngeal cultures. There were 362 serologic tests for syphilis done at the initial visit, and 1.7% were positive.

Motile sperm were present in the wet preparation from the vagina in 17% of the victims. In 26%, nonmotile sperm were seen. In only two cases were sperm identified on the wet preparation while the permanent stain was read as negative. There were 44 cases where the wet preparation was negative and the permanent stain positive.

While in the emergency room, 69% of the victims expressed a desire to pursue prosecution if a suspect could be arrested. Of these, 10% later changed their mind and dropped charges. The individual reasons the victim had for not wishing to prosecute did not correlate with age or race. Neither was her knowing the assailant or sustaining injury during the assault related to this decision. If a weapon was used, however, the victim desired prosecution more often (79% versus 55%). The age and race of the victim did not alter her

likelihood to change her mind and later drop charges; neither did her relation to the assailant or his use of a weapon.

Of the 243 victims who persistently desired to prosecute, a suspect was arrested in 132 of the cases. Thus for 46% prosecution was desired but a suspect was never arrested. If an arrest was made, 53% occurred within 24 hours after the assault, 70% by the first week. A suspect was arrested more often if the victim was a child, knew her assailant, or was physically injured during the assault. The frequency with which an arrest was made did not correlate with the victim's age, race, or marital status or with her having a history of a mental health problem.

Only 16% of the victims ever returned to the gynecology clinic for a follow-up visit. The personnel at the Victim Intervention Program, however, were able to contact and follow up on at least 85% of the cases. In 63% they met with the victim on multiple occasions. Of the 249 women with follow-up data available, 37% suffered significant psychiatric complications warranting referral for more intensive psychotherapy. Those women who did develop signifcant psychiatric complications were more likely to have a previous history of a mental health problem (71% versus 19%).

Comment

These data came from women who chose to report the assault. Since many sexual assaults are probably not reported,[6] one may not extrapolate conclusions from this study to all rape events as a whole. For example, the data suggest black women are more likely per capita than white women to sustain a sexual assault. This could result from more black women per capita being assaulted or from reluctance of white victims to report the event and be seen in the county hospital.

On comparison of the data concerning rape in Memphis, Tennessee, reported by Solola et al.[2] and the State Center for Health Statistics,[7] one finds that in Memphis 3.5 per 1000 women aged 16 to 30 reported being raped in 1980, while in Nashville that figure was 1.9 per 1000. Is this higher per capita rate simply because black women seem more likely to be raped and Memphis has a larger percentage of blacks? If the racial distribution of 16- to 30-year-old women in Memphis were the same as that in Nashville, then with the use of demographic standardization the overall rate in Memphis would be 2.1 per 1000. However, this figure was 3.5 per 1000, suggesting some other factor must be involved. Another approach to this question is to compare the per capita rates for black women in the two cities. For 1980, 1.4 per 1000 black women of all ages reported being raped in Nashville, while in Memphis that figure was 2.4 per 1000. Futhermore, in Nashville 0.7 per 1000 white women of all ages reported rape in 1980, while in Memphis this number was 0.9 per 1000. Thus for both races a larger number per capita reported being raped in Memphis. This could be because male citizens of Memphis are more prone to committing rape than those of Nashville. It seems likely however, that the use of a noninstitutionalized rape center in Memphis is more encouraging for victims to report the event and seek treatment.

Comparing other characteristics of the assault event in Nashville with those for Memphis[2] and other cities,[1, 3-5] one finds consistency in the reported distribution of the victim's age, the lcoation of the assault, the use of a weapon and the type of weapon, the relation of the victim to the assailant, the number of cases involving multiple assailants, the site(s) of forced penetration during the assault, and the most frequent time of day. Nashville differed from Memphis in that 41% of our victims suffered some form of nongenital injury, while only 23% were so injured in Memphis. This difference may be because rape in Memphis is less violent than in Nashville but again is probably because a victim without physical injury is more likely to report the event and seek treatment if she does not have to go to a county hospital emergency room for care.

Although one in every five patients in our series reported having been victim of a previous sexual assault, 66% of these women aged 16 or older also had a history of some sort of mental illness. This correlation was not because "crazy people make up stories"; the percent of victims with objective evidence of violence (injury) and penetration (sperm in the vagina not accounted for by voluntary coitus) was the same whether or not the victim had a history of mental illness. These individuals are more vulnerable to repeated sexual abuse perhaps because of their housing arrangements, because they have an impaired judgment of character, and/or because they have decreased defense capacities. Along this line, almost one fourth of recurrent assault victims were assaulted by someone well known to them whereas only 1% of first-time victims knew their assailant well. Again, recurrent assault victims seem somehow to suffer from an increased vulnerability. Women over 40 years old and black women were also more likely to have been victims of a previous sexual assault. This correlation persisted after exclusion of those with a history of a mental health problem and could not be accounted for simply by compounding the chance of a single random event as the patient aged or simply because black women have an overall higher per capita assault rate than white women and would therefore be more likely to be assaulted more than once. It may be that older women and black women are more likely to live alone and are perceived as easier targets by the rapist.

When reporting on a similar series from Toronto in 1977, Clark and Lewis[8] stated that women who were

young, were single or divorced, were on welfare, or had a history of a mental health problem were unlikely to have the police follow through with the case and make an arrest. They concluded that the police did not take the case seriously and they categorized these victims as "women who cannot be raped." The data from Nashville in the 1980s do not repeat this finding. The likelihood that an arrest was made for cases where the victim desired to press for prosecution was not influenced by her age, race, being single or divorced, or having a history of a mental health problem. This may be because a Sexual Crimes Unit that was established by the Police Department was specially trained and sensitized to the issues involved in sexual assaults. Victims who were children or who knew their assailant casually or well were more likely to have a suspect arrested than those for whom the assailant was a total stranger. This was probably because these assailants were easier to locate and identify. The other factor that did correlate with the likelihood of arrest was whether the victim sustained nongenital injury. Victims who were "beaten up" and desired prosecution were more likely to have an arrest made than those without this objective evidence of violence (52% versus 35%), and this was independent of whether the victim knew her assailant.

Only 59% of these victims persistently desired to prosecute a suspect if he could be arrested. Most commonly, the victim was reluctant to become involved in long court proceedings and the attendant publicity involved. This reluctance was similar despite the victim's age or race or whether the assailant was a total stranger or someone she knew. Even victims who were beaten were no more likely to desire prosecution than those without such injury. One variable that did correlate with the victim's desire to prosecute was the assailant's use of a weapon. In such cases, especially in those more than 30 years old, the victims were 24 percentage points more likely to press for prosecution than when no weapon was involved. Why weapons overcame the victim's reluctance to prosecute may be related to her feeling an intense trauma, a deeper sense of fear she would be murdered, and a more profound anger than when the assailant used no weapon. His use of a weapon could also deepen the victim's sense that she was not at fault, that the assailant's motives were corrupt from the start, and that more people would believe her claim that she was in fact raped.

The plight of the victim during court proceedings has been popularized, but this has also spread the unwanted result of women feeling that any attempt to bring the rapist to justice is useless and doomed to failure. There may be many good reasons a victim chooses not to prosecute, but a defeatist attitude does not serve the needs of women. In Nashville, special services are available to victims through the criminal justice system and the Rape and Sexual Abuse Center to assist and encourage those who choose to prosecute their assailant. Hopefully, this support will help overcome the sense of shame and helplessness felt by victims of rape and will help law enforcement agencies apprehend rapists and bring them to justice.

Less withdrawal bleeding: another reason for OGEN® (estropipate)

In a 3-month comparative trial[1] OGEN and a progestogen* induced less withdrawal bleeding than did conjugated estrogens and a progestogen.*

It's just one more reason why OGEN is so easy to start with, and so easy to stay with.

Percentage of women without withdrawal bleeding, taking either OGEN 1.25 or conjugated estrogens 0.625 mg [1]

*Both regimens were given 24 days out of 30, with levonorgestrel 0.03 mg, a progestogen, added from the 15th to 24th day.

OGEN®
(estropipate)

Only estrone. Identical to the body's own.

Scored tablets make precise dosing easy

OGEN .625
(estropipate 0.75 mg, calculated as sodium estrone sulfate 0.625 mg)

OGEN 1.25
(estropipate 1.5 mg, calculated as sodium estrone sulfate 1.25 mg)

OGEN 2.5
(estropipate 3 mg, calculated as sodium estrone sulfate 2.5 mg)

OGEN 5
(estropipate 6 mg, calculated as sodium estrone sulfate 5 mg)

OGEN tablets are scored so you can adjust dosage without writing a new prescription. It's another reason more physicians are prescribing OGEN.

OGEN®
(estropipate)

Only estrone. Identical to the body's own.

See adjacent page for brief summary of prescribing information.

OGEN®

ESTROPIPATE TABLETS, USP

Tablets

WARNING:

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. OGEN SHOULD NOT BE USED DURING PREGNANCY.

According to some investigators, the use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. Studies have reported that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. In one of these studies, this risk was estimated as not greater than 4 per 1000 exposures. Furthermore, there are reports that a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these reported changes are histologically benign, the investigators have not determined whether they are precursors of adenocarcinoma.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies in the offspring, including heart defects and limb reduction defects. One case control study estimated a 4.7 fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. OGEN has not been studied for these uses, and therefore should not be used during pregnancy. There is no evidence from well controlled studies that progestogens are effective for these uses.

If OGEN (estropipate tablets) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the question of continuation of the pregnancy should be addressed.

INDICATIONS AND USAGE

The cyclic administration (See "DOSAGE AND ADMINISTRATION" section) of OGEN (estropipate tablets) is indicated for the treatment of estrogen deficiency associated with:

1. Moderate to severe *vasomotor* symptoms of menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.

OGEN (ESTROPIPATE TABLETS) HAS NOT BEEN TESTED FOR EFFICACY FOR ANY PURPOSE DURING PREGNANCY. SINCE ITS EFFECT UPON THE FETUS IS UNKNOWN, IT CANNOT BE RECOMMENDED FOR ANY CONDITION DURING PREGNANCY (SEE BOXED WARNING).

CONTRAINDICATIONS

OGEN should not be used in women with any of the following conditions:

1. Known or suspected cancer of the breast.
2. Known or suspected estrogen-dependent neoplasia.
3. OGEN may cause fetal harm when administered to a pregnant woman. OGEN is contraindicated in women who are or may become pregnant (See Boxed Warning).
4. Undiagnosed abnormal genital bleeding.
5. Active thrombophlebitis or thromboembolic disorders.
6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. *Induction of malignant neoplasms.* Long-term continuous administration of natural and synthetic estrogens in certain animal species has been reported by some investigators to increase the frequency of carcinomas of the breast, cervix, vagina, and liver. There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning).

At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. Therefore, caution should be exercised when administering estrogens to women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. Careful breast examinations should be performed periodically.

2. *Gall bladder disease.* A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens, similar to the 2-fold increase previously noted in users of oral contraceptives. In the case of oral contraceptives, the increased risk appeared after two years of use.

3. *Effects similar to those caused by estrogen-progestogen oral contraceptives.* There are several serious adverse effects of oral contraceptives, most of which have not, up to now, been documented as consequences of postmenopausal estrogen therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women. It would be expected that the larger doses of estrogen used to treat postpartum breast engorgement would be more likely to result in these adverse effects, and, in fact, it has been shown that there is an increased risk of thrombosis in women receiving estrogens for postpartum breast engorgement.

a. *Thromboembolic disease.* It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism; it should also be discontinued during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. *Hepatic adenoma.* Benign hepatic adenomas appear to be associated with the use of oral contraceptives. Although benign, and rare, these may rupture and cause death through intraabdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations but should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The relationship of this malignancy to these drugs is not known at this time.

c. *Elevated blood pressure.* Increased blood pressure is not uncommon in women using oral contraceptives. There is now a report that this may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used.

d. *Glucose tolerance.* A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. *Hypercalcemia.* Administration of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

PRECAUTIONS

A. General Precautions.

1. A complete medical and family history should be taken prior to the initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.

2. Fluid retention — Estrogens may cause some degree of fluid retention. Therefore, patients with conditions such as epilepsy, migraine, and cardiac or renal dysfunction, which might be influenced by this factor, require careful observation.

3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc.

4. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.

5. Preexisting uterine leiomyomata may increase in size during estrogen use.

6. The pathologist should be advised of the patient's use of estrogen therapy when relevant specimens are submitted.

7. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving estrogen-containing oral contraceptive therapy. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.

8. Estrogens may be poorly metabolized in patients with impaired liver function and they should be administered with caution in such patients.

9. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency.

B. Information for the Patient. See text of Patient Package Insert which appears after PHYSICIAN REFERENCES.

C. Drug Interactions. The concomitant use of any drugs which can induce hepatic microsomal enzymes with estrogens may produce estrogen levels which are lower than would be expected from the dose of estrogen administered.

The use of *broad spectrum antibiotics* which profoundly effect intestinal flora may influence the absorption of steroidal compounds including the estrogens.

Diabetics receiving *insulin* may have increased insulin requirements when receiving estrogens.

Laboratory Test Interference. Certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following similar changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Abnormal glucose tolerance test results.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

D. Carcinogenesis. Studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods (see Boxed Warning). At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. (See "WARNINGS" section.)

E. Pregnancy. Pregnancy Category X. See "CONTRAINDICATIONS" section and Boxed Warning.

F. Nursing Mothers. Estrogens have been reported to be excreted in human breast milk. Caution should be exercised when OGEN is administered to a nursing woman.

G. Pediatric Use. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete.

ADVERSE REACTIONS

(See Warnings regarding reports of possible induction of neoplasia, unknown effects upon the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions in decreasing order of severity within each category have been reported with estrogenic therapy, including oral contraceptives:

1. *Genitourinary system.*
Increase in size of uterine fibromyomata.
Vaginal candidiasis.
Cystitis-like syndrome.
Dysmenorrhea.
Amenorrhea during and after treatment.
Change in cervical eversion and in degree of cervical secretion.
Breakthrough bleeding, spotting, change in menstrual flow.
Premenstrual-like syndrome.
2. *Breast.*
Tenderness, enlargement, secretion.
3. *Gastrointestinal.*
Cholestatic jaundice.
Vomiting, nausea.
Abdominal cramps, bloating.
4. *Skin.*
Hemorrhagic eruption.
Erythema nodosum.
Erythema multiforme.
Hirsutism.
Chloasma or melasma which may persist when drug is discontinued.
Loss of scalp hair.
5. *Eyes.*
Steepening of corneal curvature.
Intolerance to contact lenses.
6. *CNS.*
Chorea.
Mental depression.
Migraine, dizziness, headache.
7. *Miscellaneous.*
Aggravation of porphyria.
Edema.
Reduced carbohydrate tolerance.
Increase or decrease in weight.
Changes in libido.

OVERDOSAGE

Numerous reports of ingestion of large doses of estrogen-containing oral contraceptives by young children indicate that serious ill effects do not occur. Overdosage of estrogen may cause nausea and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION

1. *Given cyclically for short-term use:*

For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., 3 weeks on and 1 week off).

Attempts to discontinue or taper medication should be made at 3 to 6 month intervals.

Usual dosage ranges:

Vasomotor symptoms —One OGEN .625 Tablet to one OGEN 5 Tablet per day. The lowest dose that will control symptoms should be chosen. If the patient has not menstruated within the last two months or more, cyclic administration is started arbitrarily. If the patient is menstruating, cyclic administration is started on day 5 of bleeding.

Atrophic vaginitis and kraurosis vulvae — One OGEN .625 Tablet to one OGEN 5 Tablet daily, depending upon the tissue response of the individual patient. The lowest dose that will control symptoms should be chosen. Administer cyclically.

2. *Given cyclically:*

Female hypogonadism; female castration; primary ovarian failure.

Usual dosage ranges:

Female hypogonadism — A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. The lowest dose that will control symptoms should be chosen. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium. If satisfactory withdrawal bleeding does not occur, an oral progestogen may be given in addition to estrogen during the third week of the cycle.

Female castration and primary ovarian failure —A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. Adjust dosage upward or downward according to severity of symptoms and response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED

OGEN (estropipate tablets, USP) is supplied as OGEN .625 (0.75 mg estropipate), yellow tablets, **NDC** 0074-3943-04; OGEN 1.25 (1.5 mg estropipate), peach-colored tablets, **NDC** 0074-3946-04; OGEN 2.5 (3 mg estropipate), blue tablets, **NDC** 0074-3951-04; and OGEN 5 (6 mg estropipate), light green tablets, **NDC** 0074-3958-13. Tablets of all four dosage levels are standardized to provide uniform estrone activity and are grooved (Divide-Tab®) to provide dosage flexibility. All tablet sizes of OGEN are available in bottles of 100.

Abbott Pharmaceuticals, Inc.
North Chicago, Illinois 60064

Detailing the latest diagnostic procedures and therapeutic approaches to three critical problems . . .

REPRODUCTIVE FAILURE

Edited by **Alan H. DeCherney,** MD
With 15 contributors

This comprehensive book offers **complete coverage of infertility and reproductive wastage.** It addresses all aspects of human reproductive failure, both those related to conception and those occurring after conception, including spontaneous abortion, habitual abortion, and ectopic pregnancy. The emphasis is on detailed clinical descriptions of various disease entities along with applications of basic science information to the development of effective treatment approaches. Also includes coverage of the infertile couple, i.e., diagnosis and treatment of the male and female, both by correction of a physiological deficit, such as induction of ovulation, or by treatment of a specific disease entity, such as endometriosis.

1986. 308 pages. 93 illustrations, 47 tables. $45.00

BREAST DISEASE

Edited by **Douglas J. Marchant,** MD
With 11 contributors
Volume 1, *Contemporary Issues in Obstetrics and Gynecology*

Premier volume in this vital new series provides a timely update on the diagnosis and treatment of breast disease and breast cancer, and the responsibilities of the obstetrician/gynecologist in treating these conditions. Provides a detailed discussion of the known risk factors and current hypotheses on the etiology of breast cancer with special attention given to its endocrinology and analytic epidemiology. Discusses the role of the primary physician and current medicolegal issues. Also covers various treatment options: estrogen-progestogen therapy . . . surgery . . . radiotherapy for operable breast cancer . . . chemotherapy.

1986. 169 pages. 53 illustrations, 28 tables. $37.00

ULTRASOUND IN PERINATOLOGY

Edited by **Nabil F. Maklad,** MD PhD
With 20 contributors
Volume 19, *Clinics in Diagnostic Ultrasound*

This amply illustrated volume details the increasing use of ultrasound in the fields of obstetric and neonatal diagnosis and management. Describes how sonographic methods can be used to determine menstrual age, and measure fetal growth and IUGR; identify the causes, diagnosis, and management of NIH and related conditions; study the fetal brain and abdomen, and evaluate the neonatal heart. Also discusses the role of BPS in the identification of the fetus at risk of death or damage *in utero* and in the overall management of the high-risk pregnancy; intraoperative brain and abdominal scanning and much more!

1986. 224 pages. 149 illustrations, 23 tables. $37.00

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $6.95 each, postpaid (3 for $20.00, 6 for $36.00). Add $2.50 postage per case for orders outside U. S. Prepayment must be in U. S. funds only. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

Are You Perplexed?

Do you need a *physiological* parameter for diagnosing IUGR?

Normal Flow

Reduced Diastolic Flow

There is growing evidence that umbilical artery waveforms obtained with continuous wave Doppler are useful in the evaluation of placental vascular insufficiency in IUGR, hypertension, diabetes, and post-maturity. Examine the evidence in the recent literature.

CW Doppler spectral analysis is easy to perform, fast, and inexpensive. Ultrasound power levels are within acceptable limits. The ANGIOSCAN III may be used as a stand alone system or in conjunction with real-time sonography. The ratio of systolic to diastolic velocity, which is a reflection of the resistance in the placental circulation, as well as the pulsatility index and index of resistance, are automatically computed.

Call us for a free demonstration. You will be astonished at how easy it is.

We'll Demonstrate it!

the facts are known in pelvic inflammatory disease

ct: frequently polymicrobial

Pelvic inflammatory disease is frequently polymicrobial; gonococci, *Escherichia coli*, and *Bacteroides* species are frequently involved.

ct: CDC recommends broad coverage

In treating P. I.D., CDC urges the selection of regimens that are active against the broadest range of possible pathogens.

ct: can bring about infertility

Inadequate treatment can lead to tubal stricture—the major cause of involuntary infertility and an important cause of ectopic pregnancy.

FOXIN® (Cefoxitin Sodium, MSD) is contraindicated in ents who have shown hypersensitivity to cefoxitin and the halosporin group of antibiotics. Before therapy with MEFOXIN is tuted, careful inquiry should be made to determine whether the ent has had previous hypersensitivity reactions to cefoxitin, halosporins, penicillins, or other drugs. This product should be given with tion to penicillin-sensitive patients.

Unruptured ampullary ectopic pregnancy.

and in the treatment of P.I.D.†

the facts still favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

PROVEN* FOR 7 SEVEN YEARS

fact: consistent spectrum of activity**

MEFOXIN has maintained a high level of activity against common pathogens in P.I.D. during 7 years of extensive clinical use.

fact: documented clinical efficacy

CDC has recommended that MEFOXIN, in combination with doxycycline, be one of the regimens for the treatment of P.I.D.

fact: safety comparable to cephalothin

MEFOXIN is generally well tolerated. MEFOXIN does not contain the MTT side chain which has been associated with hypoprothrombinemia and, in some cases, clinical bleeding.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

†MEFOXIN is indicated for the treatment of pelvic inflammatory disease caused by *Escherichia coli*, *Neisseria gonorrhoeae* (penicillinase- and non-penicillinase-producing), *Bacteroides* species including the *Bacteroides fragilis* group, *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and Group B streptococci. MEFOXIN is not indicated for treatment of pelvic inflammatory disease where *Chlamydia trachomatis* is present or suspected.

*proven for treatment of, and prophylaxis against, infections due to indicated organisms

***In vitro* activity does not necessarily imply *in vivo* effectiveness.

MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see following page.

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST ‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials and infusion bottles containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

Ultrasound evaluation of polyhydramnios and twin pregnancy

Beverly Hashimoto, M.D., Peter W. Callen, M.D., Roy A. Filly, M.D., and Russell K. Laros, M.D.

San Francisco, California

We analyzed the ultrasound examinations and medical records of 75 pairs of twins who were delivered between January, 1983, and December, 1984, to study the relationship between increased amniotic fluid volume, fetal abnormalities, and preterm labor. Ten of these 75 twin pregnancies demonstrated elevated amniotic fluid volume that persisted throughout pregnancy. Total intrauterine volumes were elevated in these cases, and nine of the ten pregnancies were abnormal. In addition, it was noted that elevation of the amniotic fluid volume alone did not explain the high rate of preterm labor and delivery in twin gestations. (Am J Obstet Gynecol 1986;154:1069-72.)

Key words: Twins, polyhydramnios, abnormalities in twins, premature labor

Ultrasonographic identification of twin pregnancies is important because these pregnancies have much higher morbidity and mortality in comparison with singleton gestations.[1] Besides identification of twin gestations, ultrasound is also useful in assessing fetal well-being.[2] One well-known complication of twin pregnancy is increased amniotic fluid volume. Although polyhydramnios in singleton gestations has long been considered a possible ominous finding associated with multiple maternal and fetal complications,[3-6] there is a general perception that polyhydramnios in twins is a common, normal event.[7] We reviewed our 2-year experience to assess the frequency of polyhydramnios in our twin population and to determine whether the presence of polyhydramnios in twin pregnancies was associated with fetal abnormalities or could explain the increased incidence of preterm labor in twin gestations.

Material and methods

We reviewed the medical records and ultrasound examinations of all twin pregnancies in which either delivery or sonographic study took place at our institution from January, 1983, to December, 1984. A total of 86 twin pregnancies were identified. Eleven pregnancies were excluded for the following reasons: fetal death in the first trimester (two), and only one sonogram performed at our institution at less than 10 menstrual weeks (four), twins not suspected prenatally, so that no sonogram was performed (one), or medical records unavailable from the referring institution (four). Therefore 75 patients for whom both ultrasound examinations and delivery records were available were the basis for our study.

The medical records and ultrasound examinations were reviewed to ascertain presence of polyhydramnios, occurrence of preterm labor, congenital abnormalities, and referral source of the patient. The ultrasound examinations were the basis for determining the presence of polyhydramnios. We subjectively diagnosed "increased amniotic fluid volume" if the fetal body was completely separated from the anterior part of the uterine wall. Total intrauterine volumes were then calculated in all pregnancies in which there were adequate longitudinal and transverse static images obtained by a standard method previously described.[8] Total intrauterine volumes were obtainable in 55 of 75 pregnancies. Of 18 patients who were diagnosed subjectively as having increased amniotic fluid, total intrauterine volumes could be determined for 15 patients. The remaining three had gross polyhydramnios but could not be transported for static B scans. Our total intrauterine volumes were then compared with previously published total intrauterine volume data on twins.[9] Polyhydramnios was diagnosed only if the total intrauterine volume was elevated (above the normal standards set previously for twin gestations).[9]

Preterm labor was diagnosed if the medical record indicated significant contractions with ruptured membranes or cervical change before 37 menstrual weeks. All the women determined to have preterm labor were admitted and medically treated for variable periods. Since we were specifically interested in identifying those pregnancies that resulted in spontaneous preterm delivery, we excluded six patients in whom labor was induced: four because of severe fetal congenital anom-

alies, one because of maternal preeclampsia, and one because of therapeutic abortion in the early second trimester.

Since our institution is a referral center, we reviewed medical records to determine the source and reason for referral in each case. The reasons for referral by outside physicians included suspicion of fetal abnormality by outside ultrasound examination, preterm labor or preterm rupture of membranes, and polyhydramnios.

Results

Increased amniotic fluid volume was diagnosed by visual inspection in 18 of 75 patients. Of these 18 patients, eight had transient increased amniotic fluid volume that resolved later in pregnancy (Fig. 1). The other 10 patients maintained elevated amniotic fluid volumes throughout pregnancy. We were able to calculate total intrauterine volumes for all eight patients with transient visual increase in amniotic fluid volumes and for seven of the ten patients with persistently elevated amniotic fluid volumes. The eight patients with transient increased amniotic fluid volume each had normal or upper limits of normal total intrauterine volumes. However, the seven patients with persistently elevated amniotic fluid volume all had abnormal total intrauterine volumes. The remaining three patients with persistently elevated amniotic fluid volumes were also placed in the polyhydramnios group, even though total intrauterine volumes could not be determined. Total intrauterine volumes were also calculated for 40 of the 57 patients who did not appear to have polyhydramnios. All of these patients had normal total intrauterine volumes.

Of the 75 pregnancies in our study, 13 were abnormal (Table I). In five pregnancies, one twin was in a polyhydramniotic sac and the other twin was in an oligohydramniotic sac.[10] The twin in the oligohydramniotic sac was usually growth retarded, and the other twin usually developed hydrops.[10] These cases are all presumed to be twin transfusion syndrome, although unambiguous pathologic or clinical confirmation could not always be obtained. Abnormal pregnancies other than cases of an oligohydramniotic sac in one twin involved fetuses with congenital anomalies. Congenital anomalies present in our series included acardiac, acephalic parabiotic twins (two fetuses), conjoined twins (two pairs of twins), diaphragmatic hernia (one fetus), bladder outlet obstruction (one fetus), abnormally formed hands (one fetus), and ambiguous genitalia (one fetus). Polyhydramnios was present in only one pregnancy with normal fetuses.

In the group with "transiently increased amniotic fluid volume," there were no abnormal fetuses. The lack of abnormal pregnancies and the persistently normal total intrauterine volumes indicate that poly-

hydramnios should not be considered in such pregnancies; rather, visual clues suggesting polyhydramnios in singleton pregnancies are too stringent to be applied to twins during certain phases of pregnancy development.

In our study, 44 of 75 women (59%) developed preterm labor, and 33 of these (44%) had preterm delivery. A χ^2 analysis of the relationship between preterm labor and delivery and patients with either polyhydramnios or transient amniotic fluid elevation showed no significant relationship between these factors (Table II).

Of the 75 patients in the study groups, 20 were referred from outside rather than through our own outpatient clinical practice. The reasons for referral included suspicion of fetal anomaly (nine patients), preterm labor or preterm rupture of the membranes (nine), and polyhydramnios (two). None of the eight patients with transient amniotic fluid elevation was referred, and only two of the ten patients with persistent polyhydramnios were referred specifically because of a suspicion of increased amniotic fluid. Among the nine patients referred because of a suspicion of a fetal anomaly, there were seven pregnancies with a documented anomaly, in one a "stuck twin" phenomenon was present, and one pregnancy was normal. Of these nine patients, five had polyhydramnios. Among 44 patients with preterm labor, nine were referred for either preterm labor or premature rupture of membranes. All of these referred patients experienced preterm delivery.

Comment

Polyhydramnios in singleton gestations has generally been defined as greater than 2 L of amniotic fluid within the gestational sac.[3, 5, 11] In the past, only invasive means, such as physical removal and measurement of the volume of fluid within the amniotic sac[12] or dilution measurements of amniotic fluid,[11] were available to diagnose polyhydramnios. Now with widespread availability of ultrasonography, this modality is generally used to diagnose polyhydramnios.[6]

Experienced ultrasonographers each have visual clues that alert them to the probability that a given pregnancy has an abnormally large amount of amniotic fluid. These visual clues vary throughout pregnancy because the proportional quantity of fluid in comparison with fetal size alters with progress toward term. We, as others, have successfully used such clues but have learned during the course of this study that impressions largely derived from observation of singleton pregnancies cannot be transposed to twin gestations. Obviously our subjective criteria are unique to our group. Had other criteria been utilized, such as the "8 cm rule," the results might have met with varying degrees of success. Likewise, although there was no attempt to subjectively grade the degrees of polyhydramnios, in those groups in which polyhydramnios would have been interpreted as severe, there would undoubtedly have been a correlation with an abnormally increased total intrauterine volume.

Using ultrasound for evaluating increased amniotic fluid volumes, we have identified two groups of twin pregnancies. One group had a high frequency of abnormal pregnancies. All the subjects in this group had strong visual clues suggesting polyhydramnios and abnormally high total intrauterine volumes throughout pregnancy. The other group subjects, with normal pregnancies, had visual clues suggesting elevated amniotic fluid volume in midtrimester that disappeared later in pregnancy. Moreover, total intrauterine volumes were normal in all these patients throughout pregnancy. Although the utility of measuring total intrauterine volume has been limited in some studies, this measurement appears to be useful in discriminating between those twin pregnancies in which amniotic fluid volume is normal and those in which polyhydramnios is present. It is of interest that other studies utilizing subjective methods to diagnose polyhydramnios also note similar dichotomies in their polyhydramnios groups.[6] It is recognized, however, that for many examiners the unavailability of static articulated arm equipment may not make this measurement practical.

It now seems clear that visual clues employed to diagnose polyhydramnios in singleton gestation, such as the ones used in this study, are not applicable to twin gestations. Amniotic fluid may normally occupy two thirds of the gestational sac in a singleton gestation at 20 weeks.[3] Two sacs with fluid at the upper limits of normal confined within the uterus would likely simulate polyhydramnios. Likewise it is conceivable that in those cases in which there was polyhydramnios in one sac and oligohydramnios in the other, the abnormal sac volumes might tend to neutralize one another and the total intrauterine volume might be normal. Moreover, in one of the eight cases with "transient amniotic fluid elevation," only one sac appeared to have excess fluid. This observation further supports our contention that the subjective determination of polyhydramnios in twin pregnancy is too broad. Since the calculation of total intrauterine volumes appeared to differentiate between these groups, this calculation may be useful in diagnosing polyhydramnios more strictly than a subjective method.

If one considers only the group with abnormally elevated total intrauterine volumes as having polyhydramnios, the frequency of abnormally increased fluid volume is still substantially higher than in singleton gestations (10 of 75 cases).[3, 5] Since our institution is a referral center, there was potential for referred cases to dramatically influence the prevalence of polyhydramnios in our patient population—and they did so.

Eight of twenty referred patients carrying twins had polyhydramnios, whereas only two of 55 nonreferred patients had polyhydramnios. The prevalence in our nonreferred population was only 3.6%. Previous studies have found that polyhydramnios is present in 6% to 7% of twin pregnancies.[13] When one considers that two pregnancy events occur in twinning, one would expect the prevalence of polyhydramnios to be twice that in singleton pregnancies. This is approximately correct in our nonreferred patient group.

In our patient group with clearly defined polyhydramnios (i.e., strong visual clues, persistently elevated fluid quantities, and abnormal total intrauterine volume), nine of 10 cases were abnormal. Other series have noted that 30% to 70% of twin pregnancies in which polyhydramnios is present are abnormal.[3]

Increased uterine distension has been considered one possible cause for preterm labor and delivery,[14] and this mechanism has been used to explain the increased frequency of preterm labor and delivery in multiple gestations.[15] Since polyhydramnios would cause increased distension and is thought to be common in twin pregnancies, we attempted to determine whether there is a relationship between preterm labor and delivery and polyhydramnios. The frequency of preterm delivery in our study (44%) is within the broad range of 30% to 86% found in other studies.[16] However, no statistical relationship was found between preterm delivery and polyhydramnios in our series.

In summary, polyhydramnios is not a common finding in "normal" twin pregnancies. If polyhydramnios is diagnosed, the pregnancy should be closely studied to exclude abnormalities. Although diagnosis of polyhydramnios is important, subjective sonographic estimation of fluid in twin pregnancies was difficult in our hands. We found that determination of total intrauterine volumes was more accurate in segregating twin pregnancies in which polyhydramnios is present from those in which fluid volume is at the upper limits of normal.

The role of lymphangiography in vulvar carcinoma

Sheldon A. Weiner, M.D., Joseph K. T. Lee, M.D., Ming-Shian Kao, M.D., and Thomas E. Moon, Ph.D.

St. Louis, Missouri, and Tucson, Arizona

The records of all patients with vulvar carcinoma seen at Washington University School of Medicine between 1970 and 1983 were reviewed to determine the role of lymphangiography in the management of patients with vulvar malignancy. Forty-three patients were identified who had a preoperative lymphangiogram followed by radical vulvectomy and lymph node dissection. Thirty-two films were available for review. Seventy-seven sets of lymph nodes were obtained from the 32 patients. Overall diagnostic accuracy was 42 of 77 (54.5%), with a sensitivity of three of 19 (15.7%) and a specificity of 39 of 59 (66.1%). Corresponding values for inguinal nodes were 26 of 57 (45.6%), two of 16 (12.5%), and 24 of 41 (58.5%), respectively. Accuracy rates for pelvic nodes were 16 of 21 (76.2%) with a sensitivity rate of one of three (33%) and a specificity of 15 of 18 (83%). Negative scans were more likely to be accurate than positive scans, 88.6% versus 30%. While a negative lymphangiogram may be helpful in predicting the absence of metastases, its poor specificity limits its widespread usefulness. (Am J Obstet Gynecol 1986;154:1073-5.)

Key words: Vulvar carcinoma, lymphangiography

The accepted management of invasive carcinoma of the vulva has traditionally been radical vulvectomy and en bloc resection of the regional lymphatics and inguinal lymph nodes. Recently, investigators have been attempting to define a subset of patients who might benefit from a less radical surgical approach.[1] An important adjunct to such individualized treatment planning would be the ability to detect those patients likely to have lymph node metastases. The use of lymphangiography in the preoperative workup of these patients has been controversial, with accuracy ranging from 60% to 85%.[2-7]

Bipedal lymphangiography has been part of the routine preoperative evaluation of patients scheduled to undergo radical vulvectomy and lymph node dissection at Barnes Hospital, St. Louis, Missouri. This experience has been reviewed to determine the potential role of lymphangiography in the treatment planning of patients with vulvar malignancy.

Material and methods

Patients. The records of all patients with vulvar carcinoma between the years 1970 and 1983 were reviewed. Of 58 patients, 43 were identified who had a preoperative lymphangiogram followed by a radical surgical procedure and a lymphadenectomy. Thirty-two of these patients had films available for review by one of the authors (J.K.T.L.); the radiographs on the other 11 patients were unobtainable and therefore not included in the final statistical analysis.

Technique of lymphangiography. Bipedal lymphangiography was performed in a standard fashion as reported previously.[4] Briefly, 0.5 ml of alphazurine A was injected intradermally into the web space between the first and second toes and between the third and fourth toes to facilitate the identification of lymphatic vessels. A 1-inch-long incision was made over the dorsum of the foot; a lymphatic vessel was isolated and cannulated with a 27- or 30-gauge needle. Ethiodol, 5 to 7 ml, was injected into each lymphatic vessel with an infusion pump.

Radiographs of the pelvis and abdomen in both frontal and oblique projections were made immediately after injection as well as 24 hours after the procedure.

Operative technique. Twenty-eight patients underwent the standard Basset operation—radical vulvectomy with en bloc removal of superficial and deep inguinal lymph nodes. Within this group, eight had bilateral retroperitoneal pelvic lymphadenectomies to the level of the bifurcation of the common iliac arteries. Three patients had exenterative procedures (two posterior, one anterior) that included transperitoneal pelvic lymphadenectomies. One patient had a bilateral inguinal lymphadenectomy only, having previously undergone a vulvectomy. In each patient, lymph nodes were separated both radiologically and pathologically into four groups, right and left inguinal and right and left pelvic. Diagnostic accuracy of lymphangiography was assessed by comparing radiologic findings with his-

Positive	2	10	4	16
Negative	6	11	24	41
Total	8	21	28	57

tologic findings for each of the four groups of lymph nodes.

Radiographic criteria. The following criteria were used when the lymphangiograms were interpreted: (1) A lymph node was considered to contain metastases if a nodal defect was peripheral in location, if it was 0.5 cm in diameter, or if it was not traversed by lymphatic channels. (2) A lymph node was considered to be indeterminate for metastases if it was large (>2 cm) but had no focal defect, if it had a central filling defect, or if it had a peripheral defect <3 mm in size. (3) A lymph node was considered to be negative if it had had none of these findings.

Statistics. The following definitions were used: (1) Sensitivity equals the number of positive examinations in cases with metastases divided by the number of cases with metastases. (2) Specificity equals the number of negative examinations in cases without metastases divided by the number of cases without metastases. (3) True positive examinations equal the number of cases with metastases and positive examinations divided by the number of positive examinations. (4) True negative examinations equal the number of cases without metastases and negative examinations divided by the number of negative examinations. The 95% confidence intervals were calculated where indicated.

Results

Lymphangiography correctly predicted pathologic findings in 42 of 77 cases, for an accuracy rate of 53.8%. The overall sensitivity (positive examinations in patients with metastases) was three of 19 (15.7%, with a 95% confidence interval of 4% to 39%), whereas the specificity (negative examinations in patients without disease) was 39 of 59 (66.1%, 95% confidence interval 52% to 78%) (Table I). The likelihood that a negative scan correlated with absence of metastases was 39 of 44 (88.6%, 95% confidence interval 74% to 97%), while a positive scan correctly predicted metastases in three of 10 (30%, 95% confidence interval 7% to 65%) instances.

Overall accuracy for inguinal nodes was 26 of 57 (45.6%); two of 16 (12.5%, 95% confidence interval 2% to 36%) patients had nodal metastases detected whereas 24 of 41 (58.5%, 95% confidence interval 42% to 75%) patients without disease were correctly identified (Table II). The predictability of a negative inguinal examination was 24 of 28 (85.7%, 95% confidence interval 68% to 96%), whereas a positive scan was correct in only two of eight cases (25%, 95% confidence interval 3% to 65%).

Table III. Pelvic lymphangiography

Histologic diagnosis	Radiologic diagnosis			Total
	Positive	Equivocal	Negative	
Positive	1	1	1	3
Negative	1	2	15	18
Total	2	3	16	21

The specificity and sensitivity of lymphangiography in detecting patients with pelvic node metastases, although not statistically significant, were somewhat better than in patients with inguinal node disease. The accuracy rate for pelvic nodes alone was 16 of 21 (76.2%). The specificity was 15 of 18 (83%, 95% confidence interval 58% to 96%), while the sensitivity was one of three (33%, 95% confidence interval 0% to 76%) (Table III). The predictability of a negative scan was similar to that of inguinal lymphangiography, 15 of 16 (93.75%, 95% confidence interval 70% to 100%), whereas correlation of a positive scan with the presence of metastases was difficult to determine because of small numbers (one of two or 50%, 95% confidence interval 0% to 100%).

Equivocal examinations accounted for 36.8% of all inguinal lymphangiograms but for only 14.2% of pelvic scans. Of the equivocal examinations, 54.1% were without documented metastases and 45.8% had histologic evidence of disease.

Comment

Two areas of controversy exist in the treatment of patients with invasive vulvar carcinoma. The first involves identifying those patients with "microinvasive" and "early" carcinoma who are at low risk for inguinal metastases and could be treated with a limited excision of the primary lesion.[1] The second area relates to identifying those patients with pelvic node metastases who would require alteration of regional therapy to include treatment of pelvic lymph nodes.

Lymphangiography in the evaluation of the gynecologic oncology patient has been in use since 1958,[2]

and early reports of its accuracy were quite favorable.[3,4] Subsequently, in 1965, Averette[5] reported that 61 of 82 patients (73.4%) with gynecologic cancer had accurate lymphangiographic diagnosis of nodal metastases. In 1969, Comas et al.,[6] from the same institution, reported an accuracy rate of 85% in 20 patients with vulvar carcinoma. In 1970, Hagen and Bjorn-Hansen[7] reported on 29 patients with vulvar carcinoma and found an accuracy rate of 60.5% in detecting inguinal node metastases, with 12.5% false positive and 12.5% false negative results and an equivocal rate of 14.5%.

In the current series, the sensitivity of lymphangiography in detecting lymph node metastases, either pelvic or inguinal, was extremely poor. A test that can only detect metastatic disease less than 33% of the time can hardly be considered useful in identifying patients with nodal metastases. Even in the presence of a positive scan, only 25% to 50% of patients were found to have evidence of metastatic nodal disease.

Although lymphangiography appears unable to accurately identify patients with metastases, clinical usefulness could still be claimed if patients without metastatic disease could be detected. In this regard, the examination is more accurate. Although not statistically significant, pelvic lymphangiography, with a specificity of 83%, appears to be somewhat more useful than inguinal lymphangiography, with a specificity of 58.5%. Even more important, a negative pelvic or inguinal scan has an accuracy rate of 85% to 90%. The major point of departure between pelvic and inguinal examinations appears to be that inguinal lymphangiography has a large number of equivocal examinations (36.8%), making it less useful as a diagnostic procedure. Our findings seem to be in agreement with those of a number of investigators[6-8]; interpretation of metastases to inguinal nodes is fraught with difficulty. The presence of inflammatory changes, fibrolipomatosis, incomplete filling of nodal chains, and anatomic variability all make the task of radiologic interpretation of inguinal nodes extremely difficult.

In summary, the role of lymphangiography in vulvar carcinoma is extremely limited. Its inability to detect inguinal node metastases precludes its use in identifying patients who need an inguinal node dissection. Although negative examinations are fairly accurate (85.7%), the low specificity and large number of equivocal examinations in the inguinal region would result in a large number of patients without metastases being managed as if they had metastatic disease. In regard to pelvic lymphangiography, the small numbers of patients with positive examinations and metastatic nodes make conclusions difficult, but the trends tend to indicate an inability to predict metastases. However, because the specificity of pelvic lymphangiography is somewhat higher and only 14% of examinations were equivocal, pelvic scans may have a role in identifying patients with vulvar carcinoma who are unlikely to have pelvic metastases, as a negative examination had an accuracy rate of 93.7%.

Assuming one believes that pelvic lymphadenectomy is indicated in the presence of inguinal metastases, one could use a negative pelvic lymphangiogram to exclude patients from this extended surgical procedure. Since only 20% to 25% of patients with positive inguinal nodes will have pelvic metastases,[9] a negative examination would give approximately 90% assurance that there is no metastatic disease. One could therefore avoid the more radical operation, which is associated with increased morbidity and questionable survival benefits.[9,10] If pelvic lymphadenectomy is not contemplated in the primary therapy of vulvar carcinoma, then it would appear that lymphangiography has very little role to play in the management of the patient with this disease.

Human fallopian tube contains placental protein 14

Mervi Julkunen, M.D., Torsten Wahlström, M.D., and Markku Seppälä, M.D.
Helsinki, Finland

Radioimmunoassay and immunoperoxidase staining were used to study the tissue content and localization of an endometrial protein, placental protein 14, in the human fallopian tube. Placental protein 14 immunoreactivity was found in saline extracts from all fallopian tubes tested ($n = 14$). In the fimbrial part the placental protein 14 content was higher in the secretory than in the proliferative phase ($p < 0.01$). No difference was found in the placental protein 14 content between the isthmic, ampullar, and fimbrial parts of the tube. Immunoperoxidase staining localized placental protein 14 to the ciliated and secretory epithelial cells of the mucosa in all parts of the tube regardless of the phase of menstrual cycle. The occurrence of the same protein in the endometrium and fallopian tube is compatible with the common embryonic origin from the müllerian duct of these tissues. (Am J Obstet Gynecol 1986;154:1076-9.)

Key words: Endometrial proteins, placental protein 14, human fallopian tube

Placental protein 14 belongs to a group of proteins isolated from the placenta and its membranes.[1] Placental protein 14 was recently detected in the serum of nonpregnant women, where the levels show consistent variation during the menstrual cycle.[2] Since placental protein 14 was recently found to be endometrial in origin[3, 4] and since the fallopian tubes and the uterus derive from the same embryonic source, we studied human fallopian tubes for their placental protein 14 content in various phases of the menstrual cycle.

Material and methods

Samples. Salpingectomy and hysterectomy were performed on 14 apparently healthy nonpregnant women because of uterine fibroids. None of the women received hormone treatment. After the tissues had been removed and representative specimens taken for routine histopathologic examination, additional specimens from the fallopian tubes were separated for this study. In nine cases, representative samples of the ampullar, isthmic, and fimbrial parts of the tube were fixed in formalin for immunoperoxidase staining, and in all 14 cases, specimens were obtained from the three parts for the analysis of tissue placental protein 14 content by radioimmunoassay. These tissues were immediately frozen in liquid nitrogen and stored there until tested. In 10 cases a serum sample was obtained before operation and stored at −20° C until studied. The tissues were weighed, homogenized in phosphate-buffered saline solution (pH 7.4 at 4° C) containing 175 mg/L of phenylmethylsulfonylfluoride (Merck, Darmstadt, West Germany) as a protease inhibitor, and centrifuged at 4° C (10,000 × g, 30 min). The supernatants were used for protein and placental protein 14 determinations.

Radioimmunoassays. The radioimmunoassay for placental protein 14 has been described previously.[4] Purified placental protein 14 (lot No. 120/135, Behringwerke AG, Marburg, West Germany) was iodinated by the chloramine-T method.[5] Placental protein 14 antiserum (lot No. 201ZA, Behringwerke) was used at a dilution of 1:9000. The detection limit of the assay was 8 μg/L. Apart from 1% crossreactivity with purified placental protein 12, the anti–placental protein 14 antiserum did not crossreact with any known placental or human serum protein.[1, 4] The total protein content of the tissue extracts was estimated by the Lowry method.[6] Serum progesterone was estimated by a commercial radioimmunoassay kit (Farmos Diagnostica, Oulunsalo, Finland).

Gel filtration. To find out whether placental protein 14 forms complexes or is degradated in fallopian tubal extract, 125 iodine–placental protein 14 was incubated with the extract at 37° C for 4 hours. Chromatography was carried out on a Sephadex-G100 column (60 × 1 cm, Pharmacia, Uppsala, Sweden), and the radioactivity of the fractions was counted. The molecular size of fallopian tubal placental protein 14 was estimated by gel filtration on the same column and compared with that of ^{125}I-labeled placental protein 14. The column

was calibrated with bovine serum albumin (Sigma, St. Louis) and soybean trypsin inhibitor (Boehringer, Mannheim, West Germany).

Histopathologic examination and immunoperoxidase staining. Histologic examination of the endometrial specimens was performed in order to accurately date the phase of the cycle. The immunoperoxidase staining procedure has been described elsewhere.[7]

Statistical analyses were performed by the Wilcoxon rank sum test and the Spearman rank correlation test.

Results

Placental protein 14 content in the fallopian tubes. Placental protein 14–like immunoreactivity was detected in all parts of all the fallopian tubes examined (Table I). In the fimbrial part the values were higher in the secretory than in the proliferative phase ($p < 0.01$). No difference was observed in the placental protein 14 content of different parts of the tube, and no correlation was found between the serum placental protein 14 and progesterone concentrations or between the tissue content of placental protein 14 and the serum progesterone concentration.

In radioimmunoassay, serial dilutions of purified placental protein 14 and fallopian tubal extract gave parallel dose-response curves (Fig. 1). In gel filtration, tubal placental protein 14 eluted as two peaks. The first peak represents possibly an aggregated form, whereas the second peak corresponds to the elution volume of purified ^{125}I-labeled placental protein 14. Incubation of ^{125}I-labeled placental protein 14 with tubal extract yielded a similar elution pattern (Fig. 2).

Immunohistochemical localization. The endometrium was proliferative in seven cases and secretory in another seven. The fallopian tubes did not exhibit similar morphologic changes. Irrespective of this, all the fallopian tubes contained placental protein 14 demonstrable by the immunoperoxidase method. Placental protein 14 was localized in the ciliated and secretory epithelial cells of the mucosa (Fig. 3). Staining was similar in all parts of the fallopian tube regardless of the phase of menstrual cycle.

Comment

We report here results by immunochemical and immunohistochemical methods on the occurrence of placental protein 14–immunoreactive material in the human fallopian tube. The tubal placental protein 14 content was higher in the secretory than in the proliferative phase. This is compatible with our recent observations on the endometrium.[3]

The fallopian tubes and the uterus both derive from the müllerian duct. Therefore it was not surprising to find placental protein 14 in both of these tissues. Our recent studies indicate that human secretory endometrium is capable of synthesizing placental protein 14.[3]

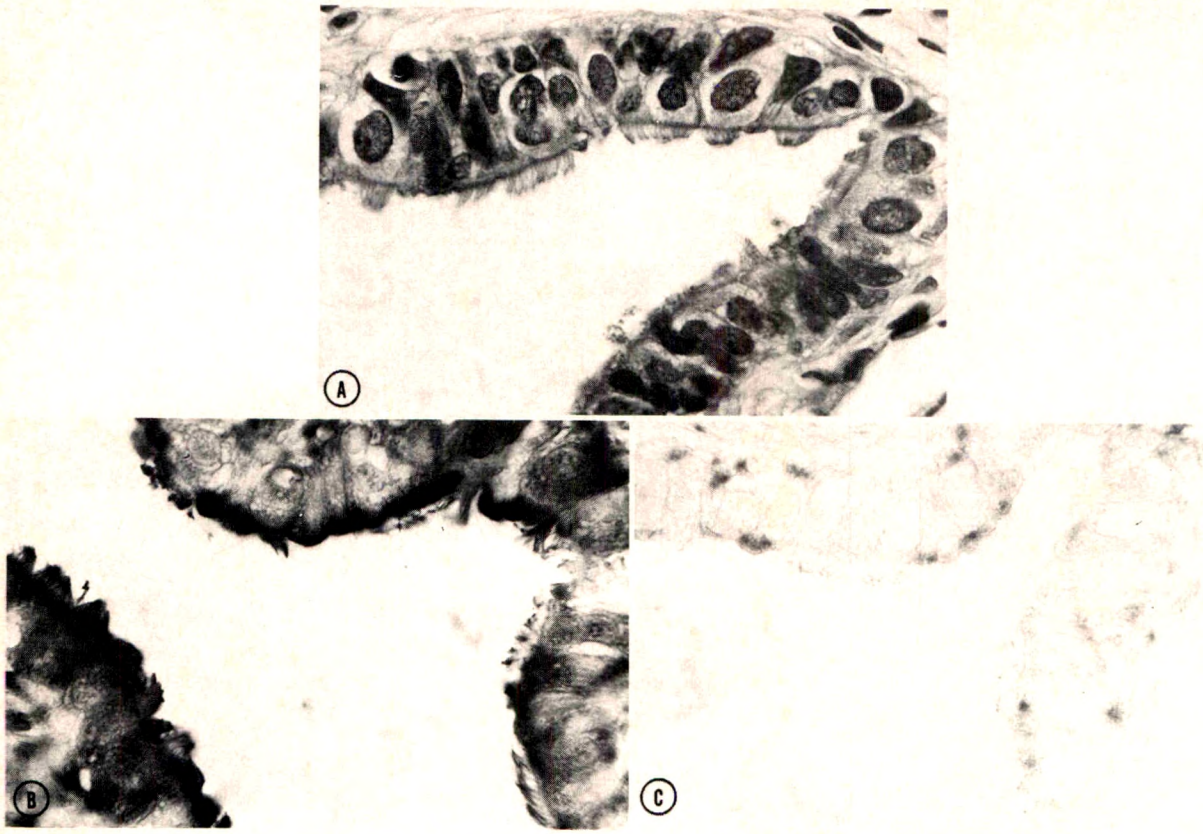

Fig. 3. Immunoperoxidase staining of fallopian tube, ampullar part. *A* shows a hematoxylin and eosin stain. In *B* the adjacent section has been stained by immunoperoxidase for placental protein 14. The positive reaction is seen both in the ciliated and the secretory epithelial cells of the mucosa. In *C* the next adjacent section has been stained with anti–placental protein 14 antiserum absorbed with purified placental protein 14 (50 μg/ml antiserum diluted 1 : 100) which blocks the stain reaction (magnification ×400).

Unlike the endometrium, the fallopian tube does not exhibit morphologic cyclic changes, and the variation of the placental protein 14 content was far less pronounced in the tube than in the endometrium. Recent comparison between placental protein 14 and progestagen-dependent endometrial protein[8] has shown that these two proteins are immunologically indistinguishable.[9] This adds interest to the occurrence of the protein in tubal mucosa. Placental protein 14 has also been identified in the fluids surrounding both the ovum and the sperm.[10, 11] It would be important to learn whether placental protein 14 in fallopian tube has anything to do with the transport of sperm or fertilized ovum.

We wish to thank Dr. Hans Bohn, Marburg, West Germany, for purified placental protein 14 and the antiserum. Technical assistance by Ms. Riitta Koistinen, M.Sc., Ms. Lea Armassalo, and Ms. Tuula Halmesvaara is gratefully acknowledged. This study was approved by the Joint Ethical Committee of Departments I and II of Obstetrics and Gynecology, Helsinki University Central Hospital.

The effect of dehydroepiandrosterone sulfate on de novo and low-density lipoprotein–stimulated progesterone secretion by human choriocarcinoma JEG-3 cells

Jacob Moise, M.D., John Ilekis, B.S., Antonio Scommegna, M.D., and Robert Benveniste, Ph.D.

Chicago, Illinois

It has been suggested that fetal adrenal steroids affect the secretion of progesterone by the human trophoblast and decrease the progesterone/estrogen secretory ratio at the time of parturition. In the present study, cultured human choriocarcinoma JEG-3 cells were used as an experimental model in order to examine the effect of dehydroepiandrosterone sulfate on both de novo and low-density lipoprotein–stimulated progesterone secretion. In serum-free and cholesterol-free Dulbecco's modified Eagle's medium, JEG-3 cell cultures demonstrated a significant secretion of both pregnenolone and progesterone. A 200% to 300% increase in pregnenolone and progesterone secretion was achieved by physiologic low-density lipoprotein concentrations added to Dulbecco's modified Eagle's medium while androgens and estrogens remained undetectable. Dehydroepiandrosterone sulfate added to Dulbecco's modified Eagle's medium was actively converted into C-19 and C-18 steroids but had no significant effect (up to 20 μg/ml) on basal (de novo) progesterone secretion. In contrast, the addition of dehydroepiandrosterone sulfate (1 to 5 μg/ml) to cultures grown in Dulbecco's modified Eagle's medium plus low-density lipoprotein induced a dose-related inhibition of progesterone and a return of that secretion to basal levels. (Am J Obstet Gynecol 1986;154:1080-5.)

Key words: Dehydroepiandrosterone sulfate, low-density lipoprotein, choriocarcinoma, progesterone

The mechanisms whereby the fetus of many species signals its readiness to enter extrauterine life involve an alteration in the fetal adrenal-trophoblast relationship. In the sheep, for example, a rise of cortisol induces changes in estrogen and progesterone secretions that are thought to be critical in increasing uterine prostaglandin activity.[1] In the human, because of the lack of 17-hydroxylase and 17,20-lyase activities in the trophoblast, the production of estrogens depends on adrenal steroids.[2,3] The possibility that dehydroepiandrosterone sulfate (DHEA-S) also influences the production of progesterone and alters the progesterone/estrogen secretory ratio at the time of parturition has been suggested.[4]

Cultured human choriocarcinoma JEG-3 cells retain several secretory characteristics of the normal trophoblast. For example, they secrete human chorionic gonadotropin (hCG), free α-subunit of hCG, and progesterone and form estrogens when a C-19 steroid precursor is added to their culture medium.[5,6] Choriocarcinoma cells also display several of the cell surface receptors observed on the normal tissue and have receptors for low-density lipoprotein (LDL), a carrier of cholesteryl esters, which are important precursors of progesterone.[7,8] In the present study, JEG-3 cells were used as an experimental model in order to examine the influence of DHEA-S on progesterone secretion. This was studied under two conditions: (1) de novo progesterone formation, when cells are grown in serum-free and cholesterol-free synthetic medium, and (2) production of progesterone dependent on preformed cholesterol after addition of LDL to the culture medium.

Material and methods

JEG-3 cells, provided by Dr. Peter Kohler (Department of Medicine, University of Arkansas, Little Rock, Arkansas), were grown in 25 cm^2 culture plastic flasks in Dulbecco's modified Eagle's medium (DMEM) enriched with 10% heat-inactivated fetal calf serum at 37° C, in a 90% air–10% carbon dioxide atmosphere.

Fetal calf serum and DMEM were purchased from Gibco Laboratories, Grand Island, New York. Before each experiment, cells were collected by scraping, seeded to replicate flasks, and fed with DMEM supplemented with 10% fetal calf serum. At 30% to 50% confluency, media were changed to fetal calf serum–free DMEM. After 2 days in that medium, cultures were refed with DMEM alone or DMEM plus various experimental agents. Unless otherwise stated, culture media were collected 24 hours later, and after addition of bovine serum albumin (2 mg/ml) were stored frozen until measured for their steroid content. The following steroids were measured by specific radioimmunoassays after extraction from culture media with ethyl ether or petroleum ether and isolation by chromatography on Sephadex LH-20 (Pharmacia, Piscataway, New Jersey) columns: progesterone, 17-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, testosterone, estrone, and 17β-estradiol. In each individual radioimmunoassay, recovery was evaluated by the addition of a trace radioactive quantity of the steroid to be measured to culture medium samples, and results were calculated accordingly. The procedure used for the above radioimmunoassays (routinely used in our clinical laboratory for the measurement of steroid levels in blood samples) has been reported.[9] The measurement of pregnenolone was performed by Dr. John Holt (Department of Obstetrics and Gynecology, University of Chicago) by means of a radioimmunoassay kit purchased from Radio Systems Laboratories, Carson, California. Samples were extracted with hexane, and pregnenolone was isolated by means of Celite microcolumns. The radioimmunoassay was performed with a rabbit antiserum raised against pregnenolone-3-monohemisuccinate coupled to human serum albumin. The cross-reactivity stated for progesterone is 1.5%, and cross-reactivities for dehydroepiandrosterone, androstenedione, testosterone, estrone, and estradiol are all below 0.01%. The cell sheets remaining in the culture flasks were washed with 0.9% sodium chloride and solubilized in 0.5N sodium hydroxide; an aliquot of each cell digest was used for protein determination.[10] Each determination represents the mean ± SEM of steroid secreted per milligram of cellular protein per 24 hours in at least three flasks, and the results shown are representative of at least three separate experiments. The two-sample *t* test was used for statistical analysis.

LDL was isolated from human male plasma according to the procedure of Goldstein and Brown.[11] Fresh LDL was prepared about every 2 weeks and stored at 4° C in a nitrogen atmosphere. The protein and cholesterol content of the LDL preparations was measured by the methods of Meulemans[12] and Allain et al.,[13] respectively. LDL was radioiodinated according to the

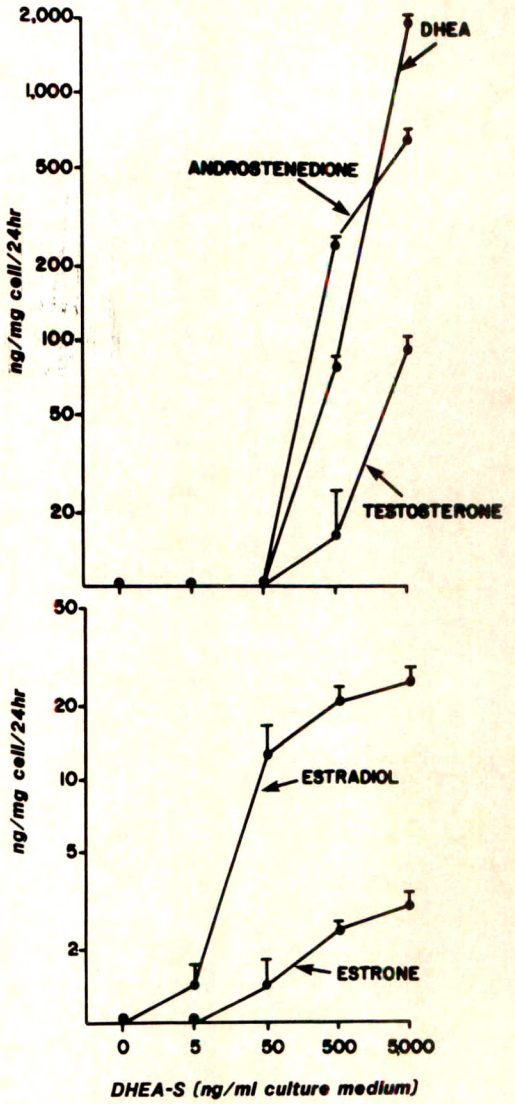

Fig. 1. Effect of DHEA-S on the secretion of C-19 and C-18 steroids by JEG-3 cells. After 3 days in serum-free DMEM, culture media were replaced by DMEM alone or DMEM plus DHEA-S. After 24 hours, media were collected for the measurement of dehydroepiandrosterone *(DHEA)*, androstenedione, and testosterone *(upper panel)* or for the measurement of estrone and estradiol *(lower panel)*, and the cell sheets were collected for protein measurement. Each point represents the mean ± SEM of three culture flasks.

procedure reported by Bilheimer et al.[14] The separation of unreacted iodine 125–labeled sodium from radiolabeled protein was achieved by means of a 24-hour dialysis (with a membrane of 3500 dalton nominal molecular weight cutoff) against 2 × 3 L of a solution containing 0.2 mol/L sodium chloride, 0.02 mol/L potassium iodide, and 0.001 mol/L ethylenediaminetetraacetic acid in water, pH 7.4, and a final dialysis against 1 L of DMEM. A specific activity of about 600 cpm/ng of protein was achieved. Uptake and degradation of [^{125}I]-LDL were evaluated at 37° C during a 24-hour

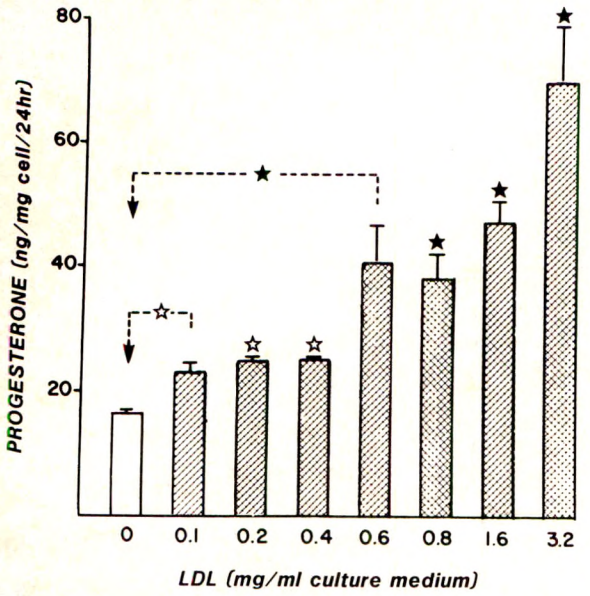

Fig. 2. Effect of LDL on progesterone secretion. After 3 days in DMEM, culture media were replaced by fresh DMEM *(open bar)* or DMEM plus LDL at various concentrations *(hatched bars)*. After 24 hours, media were collected for the measurement of progesterone (nanograms per milligram of cellular protein per 24 hours, mean ± SEM). *Open star* = $p < 0.025$; *solid star* = $p < 0.005$.

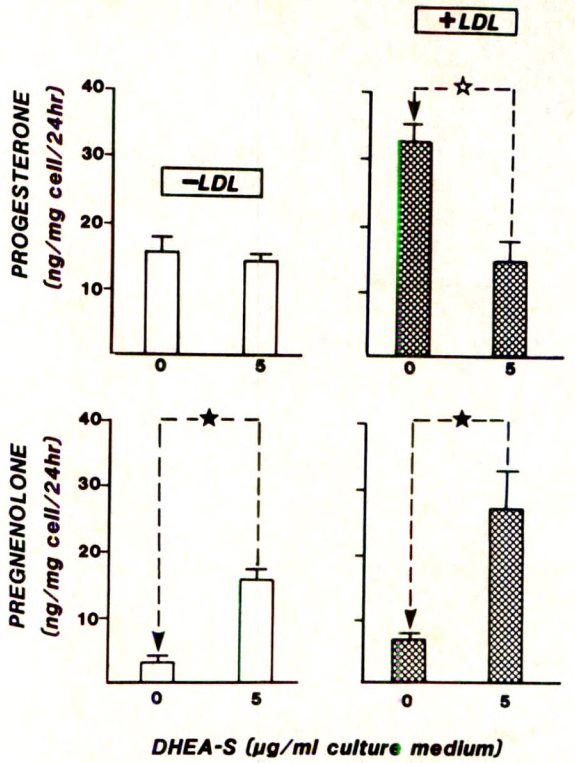

Fig. 3. Effect of DHEA-S on the secretion of progesterone *(upper panels)* and pregnenolone *(lower panels)* by cell cultures grown either in DMEM *(open bars)* or in DMEM plus LDL *(hatched bars)*. Remainder as in legend to Fig. 2.

period. Cell cultures were incubated in 3 ml of DMEM containing [^{125}I]-LDL (about 0.2 µg of protein) with or without a 500-fold excess of unlabeled LDL for the determination of nonspecific binding. At the end of the incubation period, culture media were collected, and the cell sheets were washed twice with cold saline solution. After cellular digestion with 1N sodium hydroxide, the cell radioactivity was measured. The degradation of [^{125}I]-LDL was evaluated as follows: 2 ml of cell culture medium was mixed with 0.2 ml of plasma before the addition of 0.5 ml of a 50% trichloroacetic acid solution. After 30 minutes at 4° C, proteins were collected by centrifugation. Then 20 µl of a 40% potassium iodide solution and 100 µl of 25% hydrogen peroxide were added to the supernatant. After a 5-minute incubation at 21° C, the free iodine was extracted with chloroform and the radioactivity was counted in 1.5 ml of the aqueous phase. Binding studies of [^{125}I]-LDL were performed at 4° C during an 8-hour period. Nonspecific binding was evaluated by adding an excess of unlabeled LDL. At the end of the incubation time, cell sheets were washed twice with cold saline solution and the radioactivity attached to the cells was measured in the 1N sodium hydroxide–cell digests.

Results

In synthetic medium (DMEM) alone, there was no detectable secretion by JEG-3 cells of dehydroepiandrosterone, testosterone, estrone, and estradiol (controls shown in Fig. 1). Also undetectable (<50 pg/mg of cellular protein per 24 hours) was the secretion of 17-hydroxyprogesterone (data not shown). In contrast, Figs. 2 and 3 show significant secretion of both progesterone (about 15 ng/mg of cell protein per 24 hours) and pregnonolone (about 5 ng/mg of cell protein per 24 hours).

Fig. 1 shows that the addition of DHEA-S between 5 and 50 ng/ml of DMEM induced a dose-related secretion of estrone and estradiol. At higher concentrations of DHEA-S, there was a plateau in the secretion of estrone and estradiol, at about 3 and 30 ng/mg of cell protein per 24 hours, respectively. Concentrations of DHEA-S lower than 50 ng/ml did not elicit a secretion of C-19 steroids; addition of DHEA-S above 50 ng/ml and up to 5 µg/ml induced a dose-related secretion of dehydroepiandrosterone, androstenedione, and testosterone. Fig. 4 shows the inability of DHEA-S (up to 20 µg/ml of DMEM) to affect the basal (de novo) secretion of progesterone. Although the basal secretion of progesterone was unaffected by the addition of DHEA-S, a significant stimulation of pregnenolone secretion was observed (Fig. 3, *left panels*).

The addition of LDL to DMEM resulted in a dose-related increase in progesterone secretion; a twofold to threefold stimulation of progesterone was achieved with LDL concentrations ranging between 0.6 and 3.2 mg/ml of DMEM (Fig. 2). Addition of LDL to DMEM

had no significant effect on the secretion of 17-hydroxyprogesterone or on the secretion of C-19 or C-18 steroids, the levels of which remained undetectable; also unaffected by the addition of LDL was the conversion of DHEA-S into androgens and estrogens (data not shown). The stimulation of progesterone secretion induced by LDL was abolished by the addition of 5 μg/ml of DHEA-S (Fig. 4). While suppressing the LDL-induced progesterone secretion, the addition of DHEA-S resulted in a proportional increase in pregnenolone secretion (Fig. 3, *right panels*).

The possibility that the inhibitory effect of DHEA-S on LDL-stimulated progesterone secretion resulted from an alteration of LDL binding to JEG-3 cells was evaluated at 4° C. Binding equilibrium was reached after 5 hours of incubation, and the fraction of specifically bound [^{125}I]-LDL from the total radioactivity added per culture flask (132,098 ± 1361 cpm) was not significantly different in the absence (1912 ± 214 cpm) or the presence (2185 ± 151 cpm) of DHEA-S (5 μg/ml) in the culture media. At a concentration that abolishes the stimulatory effect of LDL on progesterone secretion, DHEA-S had no significant effect on (1) the specific uptake of [^{125}I]-LDL by JEG-3 cells (Fig. 5) or (2) the quantity of specifically degraded LDL extracted from JEG-3 cell media (Fig. 6).

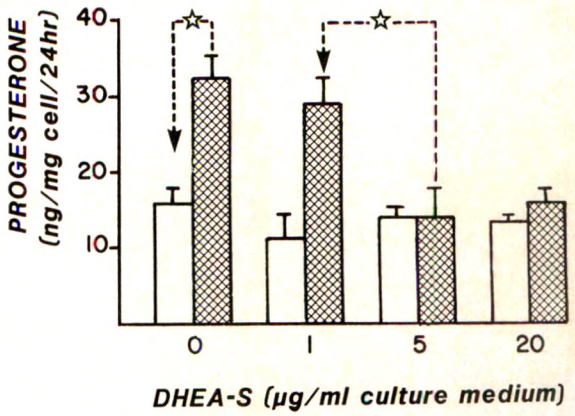

Fig. 4. Effect of DHEA-S on progesterone secretion by JEG-3 cells grown either in DMEM *(open bars)* or in DMEM + 0.7 mg of LDL protein *(hatched bars)*. Remainder as in legend to Fig. 2.

Comment

Like the normal trophoblast, JEG-3 cells have a limited capacity for hormonal storage, and a change in the 24-hour secretion reflects a change in hormonal biosynthesis (Benveniste R, unpublished data). When grown in DMEM alone, JEG-3 cells did not secrete 17-hydroxyprogesterone or C-19 or C-18 steroids; this likely reflects a deficiency in 17-hydroxylase and 17,20-lyase activities, a deficiency also present in the normal human trophoblast.[15] JEG-3 cells are similar to the normal tissue in that they metabolize DHEA-S actively; at physiologic concentrations (0.5 to 5 μg DHEA-S per milliliter), about half of the substrate was converted into dehydroepiandrosterone, androstenedione, testosterone, estrone, and estradiol.

The secretion of estradiol (and that of estrone, which represents about 10% of the secretion of estradiol) was induced by the addition of as little as 5 ng of DHEA-S per milliliter to JEG-3 cell media. Estradiol secretion increased rapidly between 5 and 50 ng of DHEA-S per milliliter but plateaued at higher DHEA-S concentrations. When estradiol plateaued, the secretion of C-19 steroids became detectable and increased with further addition of DHEA-S (Fig. 1). These results are compatible with (1) the high affinity of aromatase(s) for its substrates (Michaelis constant of 10 nmol/L, about 3 ng/ml) as reported in the normal trophoblast[16] and (2) a slow turnover of the aromatase(s) and the rate-limiting effect of that enzymatic system on the conversion of DHEA-S into estrogens.[17]

Progesterone secretion by the trophoblast has been thought to be independent of a fetal adrenal influence as evidenced by a significant progesterone secretion in anencephalic pregnancies, as well as in pregnancies where the fetoplacental circulation is interrupted.[18, 19] In 1981, this notion was challenged by Siiteri and Seron-Ferre.[4] In a study on term placentas perfused with pregnenolone, these investigators reported that about 60% of the progesterone output was suppressed by DHEA-S. Since then, others have shown that DHEA-S has some inhibitory effect and have considered it a possible mechanism by which the fetal adrenal limits the secretion of progesterone by the trophoblast.[20] The relevance of these reports was enhanced by the observation of a marked DHEA-S rise at the time of parturition in primates.[4]

In cultured human choriocarcinoma cells, LDL was shown to inhibit hydroxymethylglutaryl coenzyme A, a key enzyme in the de novo synthesis of cholesterol.[21] The ability of JEG-3 cells to grow in synthetic medium provided a rare opportunity for estimating the de novo progesterone secretion in comparison to the secretion induced by physiologic concentrations of LDL. The secretion of de novo progesterone was very significant, representing 30% to 50% of that achieved by LDL. A similar estimate on the importance of de novo progesterone secretion was obtained from studies on human fetal adrenal cell cultures.[22] It is unclear what advantage cellular steroidogenesis derives from having a complex LDL system coupled to an efficient de novo acetate-cholesterol pathway.

DHEA-S had no significant effect on the de novo secretion of progesterone. In contrast, the increase of progesterone induced by LDL was abolished by DHEA-S (at about 5 μg/ml), bringing the secretion of progesterone back to basal levels (Fig. 4). At levels where DHEA-S inhibited LDL-stimulated progester-

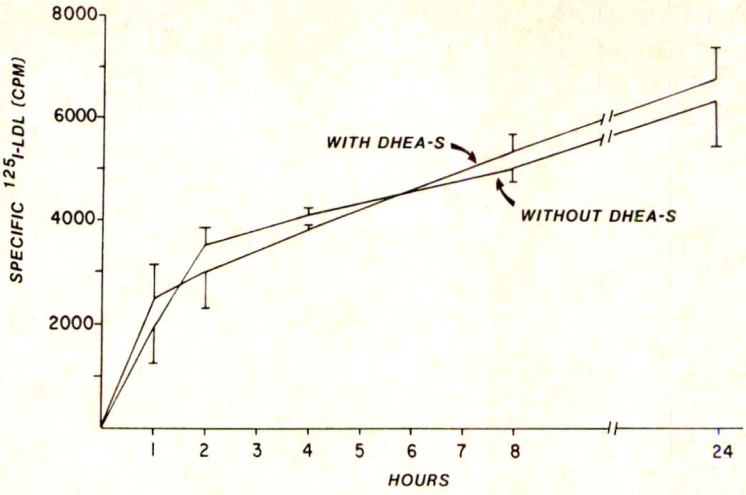

Fig. 5. Effect of DHEA-S (5 μg/ml) on the specific uptake of [^{125}I]-LDL by JEG-3 cells. After 3 days in DMEM culture media were replaced by fresh DMEM containing [^{125}I]-LDL (about 1.5 μg of protein) with or without a 500-fold excess of unlabeled LDL used for the determination of nonspecific binding. Uptake was measured at various times as indicated in Material and methods.

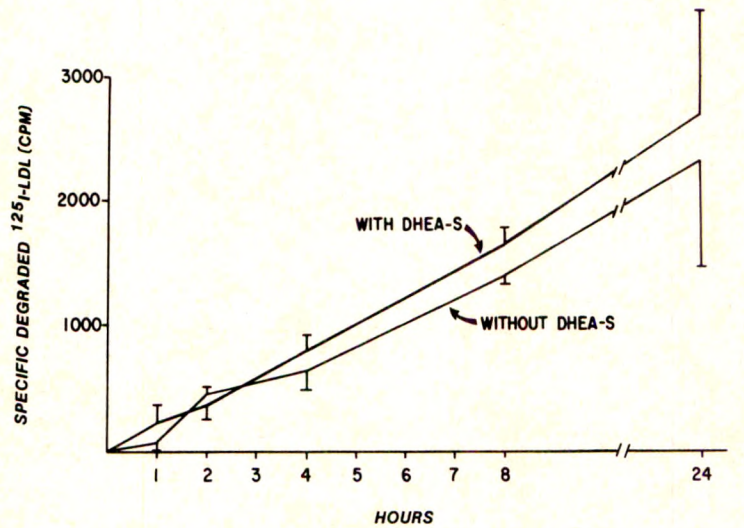

Fig. 6. Effect of DHEA-S (5 μg/ml) on the specific degradation of [^{125}I]-LDL by JEG-3 cells. Culture media corresponding to the experiment shown in Fig. 5 were measured for their content in degraded [^{125}I]-LDL as indicated in Material and methods.

one secretion, estradiol secretion remained maximum. Thus, in JEG-3 cells, a marked increase in DHEA-S is effective in altering the progesterone-estrogen secretory ratio. The differing effects of DHEA-S seen in the present study on basal versus LDL-stimulated progesterone secretion may explain the variable results with DHEA-S reported by others.[4, 20, 23] Indeed our results suggest that the response to DHEA-S would vary depending on the content of serum (or other carriers of preformed cholesterol) in the medium of the experimental model.

The possibility was first considered that ≥5 μg/ml of DHEA-S interferes with the incorporation of LDL by JEG-3 cells. Results showed that DHEA-S had no significant effect on LDL binding, uptake, or degradation (Figs. 5 and 6). Next, the inhibitory effect of DHEA-S on the conversion of pregnenolone into progesterone was considered. A marked increase of pregnenolone secretion was observed after the addition of LDL, and this increase was potentiated by DHEA-S. The effect of DHEA-S in increasing pregnenolone secretion was similar in magnitude to its inhibitory effect on progesterone (Fig. 3), suggesting that in JEG-3 cells exposed to LDL, DHEA-S inhibits 3β-hydroxysteroid dehydrogenase/Δ4,5 isomerase activity and the conversion of prenenolone into progesterone. This notion is consistent with studies on placental homogenates indicating that dehydroepiandrosterone (which is readily formed

by JEG-3 cells) competitively inhibits the conversion of pregnenolone into progesterone.[24] DHEA-S also induced a significant increase of pregnenolone in JEG-3 cells grown in DMEM alone. However, under this latter culture condition, the secretion of progesterone formed de novo was unaffected (Fig. 3). This may reflect a compensatory increase in de novo biosynthesis that follows the DHEA-S inhibitory effect on the conversion of pregnenolone into progesterone, a speculation that deserves further study.

An active form of 3β-hydroxysteroid dehydrogenase/Δ4,5 isomerase is required for the formation of both androstenedione and progesterone. In JEG-3 cells, low DHEA-S concentrations led to a secretion of C-19 and C-18 steroids, while high DHEA-S concentrations (>1 μg/ml) were needed in order to effect LDL-stimulated progesterone secretion. This suggests that in intact JEG-3 cells, 3β-hydroxysteroid dehydrogenase/Δ4,5 isomerase is coupled to two distinct functional units: one responding readily to DHEA-S and involved in androstenedione formation and a second unit affecting progesterone formation and accessed only by high DHEA-S concentrations. Lieberman et al.[25] have recently written on the cell, "hormonads," those functional units "in which reside all the components, enzymes, co-factors, etc. that are required to convert a sterol precursor to a specific hormonal product." In cells of trophoblastic origin, it is possible that 3β-hydroxysteroid dehydrogenase/Δ4,5 isomerase is located within at least two separate "hormonads," on which depends the respective control by DHEA-S of estrogens and progesterone secretion.

In summary, the exposure of JEG-3 cells to low DHEA-S concentrations establishes a basal progesterone-estrogen secretory ratio that is stable within a wide concentration range of DHEA-S. The ratio stability results from (1) a high sensitivity and rapid saturation of the enzymatic system leading to the secretion of estrogens and (2) a relatively high de novo progesterone secretion, which is unaffected by DHEA-S. Physiologic LDL concentrations increase the progesterone-estrogen secretory ratio twofold to threefold, and this increase is obliterated by raising DHEA-S to high concentrations.

The length of the human umbilical cord in vertex and breech presentations

Torgrim Soernes, M.D., and Trygve Bakke, M.D.
Nordbyhagen, Norway

The present study is based on two previously stated theories: (1) that the umbilical cord length is influenced by fetal motor activity and (2) that the breech presentation is associated with low fetal motor activity. From this one would expect the mean cord length to be shorter in breech presentations as compared with vertex. This was indeed found to be the case. An already known difference between the sexes regarding cord length was also confirmed, and a difference in male:female ratio in the two presentations is shown. The results of the study thus seem to support the two stated theories. (Am J Obstet Gynecol 1986;154:1086-7.)

Key words: Umbilical cord, vertex presentation, breech presentation

Recent research has suggested that the length of the human umbilical cord at birth is influenced by the intrauterine level of fetal activity.[1,2] The theory submitted states that linear cord growth occurs in response to tensile forces placed upon it.

Tompkins[3] assumed in his article that decreased fetal activity could be associated with breech presentation, although the evidence for this seems unclear.

If these two theories were to be verified, one would expect the length of the cord to be shorter in breech presentation as compared with vertex presentation. This study was undertaken to investigate if this difference exists.

Numerous articles have been published on the length of the human cord,[4-9] and various attempts have been made to correlate the cord length to other fetal or maternal data. Of these, only two seem to have concerned themselves with the problem of the presentation. Gardiner[4] stated that the cord must be longer in breech presentations than in vertex presentations if uncomplicated birth is to occur. However, he did not present any empirical data to support his assumption.

Malpas[6] included in his material of 538 cords only four associated with breech presentation, and he made no attempt to draw inferences from this small number.

Extensive studies have tried to correlate various maternal and fetal factors to the labor presentation.[10-14] None of these have taken the umbilical cord length into account. Those factors that were supposed to differ between breech and vertex presentations (gestational age, fetal weight) have been shown earlier not to correlate[5] or to correlate only slightly[6,8] with umbilical cord length.

To the best of our knowledge no other studies so far have been published on this subject.

Table I. Data on mean cord length

	Vertex	*Breech*	*Difference*
Mean length			
Male infants	58.46	53.78	4.68
Female infants	56.90	52.51	4.38
Differences	1.56	1.26	—

Material and methods

Between 1979 and 1983, a total of 10,887 births were recorded in our department. This figure includes both vaginal and cesarean deliveries. Stillbirths and premature deliveries as early as 28 weeks of gestation are included. We felt that this could be done confidently since previous studies have not shown any significant linear cord growth after 28 weeks of gestation.[5,6]

For the designation vertex presentation only the occipitoanterior presentation is included. All other variations of the vertex presentation are excluded. The term breech presentation includes all variations of breech. Transverse lie has been excluded. Multifetal pregnancies have been excluded.

A total of 9899 births fell into the two categories. Umbilical cords were measured in 9601 of these. In our hospital the cord is routinely cut 2 cm from the fetal abdomen. The length is then measured from this point to the placental surface.

Results

The relevant data on mean cord length are presented in Table I. All lengths are given in centimeters.

We have presented the two sexes separately. Walker and Pye[5] found that male infants had somewhat longer umbilical cords than female ones. This result is consistent with our findings in that the difference was 1.56 cm in the vertex presentations and 1.26 in the breech ones (only the former of these is significant, $p < 0.01$). Furthermore it is shown that the male:female ratios were significantly different in the two presentations ($p < 0.01$). In the vertex presentation, the male:female ratio was 1.08, which is consistent with generally accepted figures. In the breech presentation the male:female ratio was 0.85.

The distribution of the cord length was nonnormal, with a bimodal shape. This is consistent with the results of Malpas[6] and Fog[9] and is shown by the latter to be caused by the summation of two different populations: umbilical cords with coils around the fetal body and cords without any coils. The former tend to be somewhat longer. No distinctions have been made between coiled and noncoiled cords in this study.

Comment

The results show a difference between mean umbilical cord length in the vertex versus the breech presentation of approximately 4.5 cm. This supports the theory that fetuses with decreased levels of motor activity also have a tendency to assume the breech presentation at term. Whether this decreased activity is caused by some fetal factor or by intrauterine constraint is at the moment not clear. One could assume that both factors are important.

The findings that male fetuses have a slightly longer cord than female fetuses and that female fetuses tend to assume the breech presentation more often than male fetuses are also consistent with the general theory. It is, however, difficult to imagine that any external factor such as intrauterine constraint produces this effect. It seems more likely that fetal sex has a direct influence on the fetal level of spontaneous activity. On the other hand, a hitherto unknown sex-related mechanism acting directly on cord growth cannot be excluded.

A possible relation between coiling of the cord and the fetal presentation remains unknown. The sex difference in fetal motor activity, which is assumed in this article, needs further investigation. The ultimate goal would be to shed some light upon the unknown mechanisms that cause the breech presentation.

The tumor marker CA 125 is a common constituent of normal cervical mucus

Henk W. A. de Bruijn, Ph.D., Ton van Beeck Calkoen-Carpay, Siemen Jager, Ph.D., Jitze M. Duk, M.D., Jan G. Aalders, M.D., and Gert Jan Fleuren, M.D.

Groningen and Leiden, The Netherlands

The presence of the tumor marker CA 125 was studied in the cervices of healthy women. Immunohistochemical staining of normal cervical tissue demonstrated the presence of CA 125 in the tall columnar cells of the endocervical epithelium but not in the ectocervical squamous epithelium. We measured very high levels of CA 125 in liquefied cervical mucus from women with regular menstrual cycles. At midcycle, levels ranged from 14,200 to 153,000 U/ml (n = 13) in cervical mucus, while normal levels <35 U/ml were found in the corresponding serum samples. Levels of CA 125 in cervical mucus are comparable to the high levels found in cyst fluids from ovarian tumors (median 24,600 U/ml, n = 25). When secretion of cervical mucus was stimulated by ethinyl estradiol, equally high levels were found (7900 to 138,000 U/ml, n = 10). We conclude that the tumor marker CA 125 is synthesized and secreted by normal endocervical cells. Apparently an effective barrier exists between the endocervical mucosa and the circulation. (Am J Obstet Gynecol 1986;154:1088-91.)

Key words: CA 125, cervical mucus, ovarian tumor marker

CA 125 is an antigenic determinant produced by nonmucinous epithelial ovarian tumors and has been proposed as a tumor marker for patients with ovarian cancer.[1, 2] Its identity is defined by the interaction with the murine monoclonal antibody OC 125.[3] Increased serum levels of CA 125 were found in 90% of patients with manifest epithelial ovarian cancer, and rising or falling serum levels were associated with tumor progression and regression, respectively. Some patients with adenocarcinoma of the cervix or the endometrium also showed raised levels of serum CA 125.[4] It was proposed that CA 125 is a differentiation antigen, shared by fetal coelomic epithelium and its derivates in the adult, which is reexpressed in neoplastic ovarian epithelial cells.[5]

We found high levels of the antigen CA 125 in normal cervical mucus from ovulatory women and confirmed its presence in the columnar cells of the normal endocervix by immunohistochemical methods.

Methods

Patients. Twenty-three women who were patients of the Fertility Department of the University Hospital, Groningen, were examined. Thirteen women with normal menstrual cycles, biphasic basal body temperature curves, and normal viscoelastic properties of the cervical mucus were selected. Their ages ranged from 20 to 41 years. The cervical mucus samples were obtained at midcycle before ovulation, The mucus samples from 10 other women were obtained in the second week of a stimulated pill cycle. These women were prescribed 50 μg of ethinyl estradiol per day from the third to the fifteenth day after beginning of the menses. The cervical mucus was aspirated from the endocervix with the use of a long tuberculin syringe without needle. All cervical mucus samples investigated showed signs of good estrogenic stimulation. The cervical mucus samples were liquefied by sonication for 1 minute by an MSE Sonificator with a small tip. Debris was removed by centrifugation at 2000 × g for 5 minutes. The supernatants were stored at −20° C.

On the day of the cervical mucus collection blood samples were drawn from 19 of the 23 women. Blood samples were also collected from 13 women with chronic cervicitis. These women had a longer history of mucopurulent discharge from the external cervical os or contact bleeding. The diagnosis was confirmed by microscopic examination of colposcopically directed punch biopsies and material from endocervical scraping.

As a comparison CA 125 was measured in tumor cyst fluid samples and blood samples from 32 patients with epithelial ovarian tumors. These samples were collected before any treatment was started and they were centrifuged at 2000 × g for 5 minutes. The supernatants were stored at −20° C.

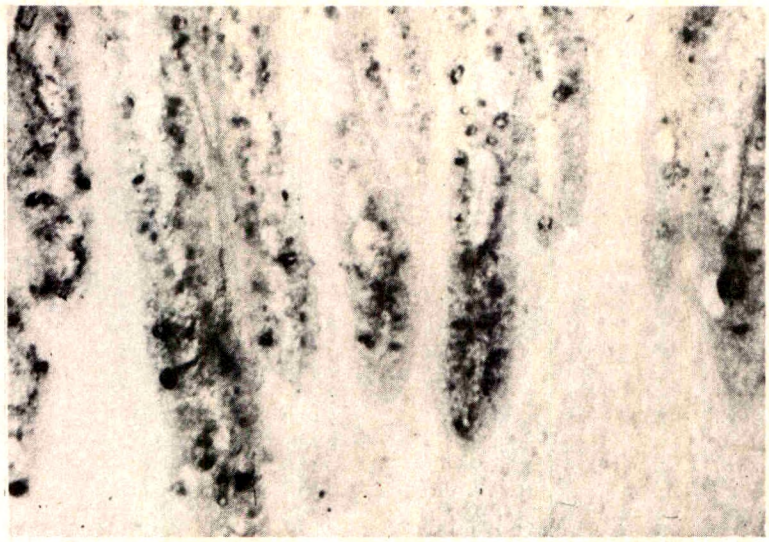

Fig. 1. Light microscopic picture of a frozen section of the endocervix incubated with monoclonal antibody OC 125. An intense staining of the endocervical cells is present. (Indirect peroxidase. Original magnification ×250.)

Measurement of CA 125. Levels of CA 125 in cervical mucus, cyst fluids, and serum were assayed with a simultaneous sandwich immunoradiometric assay as described by Bast et al.[1] The reagents were obtained from Centocor Inc. (Malvern, Pennsylvania). The extremely high levels of CA 125 in undiluted samples of cervical mucus gave an excess of antigen that blocked the iodine 125–labeled antibody, resulting in a strongly diminished binding. Therefore, multiple dilutions always up to 1/1000 were assayed for CA 125. Dilutions were made with a standard serum diluent.[1] Control measurements were done by incubation of cervical mucus samples in a two-step incubation IRMA, as described by Klug et al.[6] In this procedure the excess of antigen was removed by washing after incubation of the sample, and a separate incubation with the labeled antibody followed. All measurements were done in duplicate. Results were expressed as units per milliliter. A sensitivity of 9 U/ml was obtained. For serum samples an upper limit of normal was chosen at 35 U/ml.[1] A control serum sample was measured in 14 different assays and a variation coefficient of 8.5% was observed.

Immunohistochemistry. Endocervical tissue was obtained from autopsy or from surgical specimens of eight patients with benign or nongynecologic diseases. Their ages ranged from 13 to 87 years. CA 125 was demonstrated in snap-frozen cervical tissue blocks by the indirect peroxidase–peroxidase method essentially the same as described previously.[7] In brief, the following incubations were used: (1) Incubation was performed for 60 minutes with monoclonal antibody OC 125 (gift from Oris Lapam, France). (2) The sections were incubated with horseradish peroxidase–conjugated rabbit antimouse serum (Dakopatt, Denmark) for 30 minutes. (3) Development of peroxidase activity was performed with a freshly prepared solution of 3-amino-9-ethylcarbazole in 0.1 mol/L acetate buffer, pH 5.0, containing 0.03% hydrogen peroxide resulting in a red reaction product. Between incubations sections were washed three times for 10 minutes in phosphate-buffered saline, pH 7.4. Finally, sections were counterstained with hematoxylin for 2 minutes and mounted in Kaises glycerine gelatine (Merck, Germany).

Results

Immunohistochemical staining of normal cervical tissue demonstrates the presence of CA 125 in the tall columnar cells of the endocervical epithelium (in all eight tissue samples investigated). The staining was most intense at the luminal surfaces and the apical portion of the cytoplasm (Fig. 1). The ectocervical squamous epithelium was completely negative.

High levels of the antigen CA 125 were found in liquified cervical mucus from women with regular menstrual cycles. At midcycle, the levels ranged from 14,200 to 153,000 U/ml (Table I).

Women who received ethinyl estradiol produced a thin and clear cervical mucus with equally high levels (7900 to 138,000 U/ml). Control measurements in the two-step incubation procedure confirmed the presence of the high CA 125 levels in the mucus and an acceptable correlation was obtained ($r = 0.869$, $p < 0.001$). The level of CA 125 in cervical mucus was of the same order of magnitude as that found in cyst fluid samples derived from benign and malignant epithelial ovarian tumors (Table II).

Table I. Midcycle CA 125 levels in cervical mucus and serum from women with regular menstrual cycles

Table II. Median levels of CA 125

	No.	*Median CA 125 (U/ml)*	*Range*
Cervical mucus from preovulatory women	23	65,500	7,900-153,000
Cyst fluids from epithelial ovarian tumors	25	24,600	770-2,140,000
Serum from patients with epithelial ovarian cancer before treatment	32	424	11-4,480
Serum from healthy women	19	<35	13-35
Serum from patients with chronic cervicitis	13	<35	10-69

In serum, levels of CA 125 were below the limit of 35 U/ml in all 19 women investigated at the time of cervical mucus aspiration (Table I). Only one of 13 patients with chronic cervicitis demonstrated an elevated CA 125 level of 65 U/ml (Table II). In a control experiment we confirmed the presence of elevated CA 125 levels in preoperative serum samples from patients with epithelial ovarian cancer; in 30 of 32 patients levels >35 U/ml were seen.

Comment

Tumor antigens are used as markers in clinical oncology mainly for immunohistochemical diagnosis and monitoring of the effect of therapy. These antigens often occur in normal cells and are, so far, not tumor specific. In the search for specific antigens from ovarian cancer a monoclonal antibody OC 125 was developed that reacted with a cell line from an ovarian cystadenocarcinoma.[3] The undefined antigen was termed CA 125, and to date CA 125 has been characterized only as a high molecular weight glycoprotein.[1] Our study demonstrates the presence of CA 125 in cervical mucus and we conclude that CA 125 is a secretory product of normal cells and not a tumor-specific antigen. The production site of the CA 125 is, at least in part, the columnar endocervical epithelium, since the presence of CA 125 in the epithelial cells could be demonstrated immunohistochemically. The columnar epithelium of the endocervical canal and its diverging crypts are known to produce and secrete glycoproteins. These cells show secretory granules and irregular vacuolization characteristic of the mucin cell type. They stain deeply red with the periodic acid–Schiff method.[8] It cannot be excluded that some of the CA 125 in the cervical mucus originates from other parts of the female genital tract. Presence of CA 125 in cervical mucus due to deposition by semen could be excluded since the antigen could not be detected in seminal plasma or on spermatozoa (unpublished observations).

Despite the high levels in cervical mucus, only small amounts of CA 125 could be detected in serum from normal women. Apparently this is because an effective barrier exists between the endocervical mucosa and the circulation. We investigated serum CA 125 levels in patients with chronic cervicitis because in endocervical biopsy specimens subepithelial infiltration of lymphocytes and plasma cells is often present. This condition may enhance transfer of CA 125 into the circulation. One of the 13 patients studied showed a raised level. Niloff et al.[9] were unable to find elevated serum levels in women with vaginitis or cervicitis. However, they used 65 U/ml as the upper limit of normal. Although CA 125 is not tumor specific, it may be quite useful for monitoring the response to therapy and early detection of tumor recurrence in patients with ovarian epithelial cancer. The specificity of raised serum levels of CA 125 as an indicator of malignancy remains to be assessed.

The presence of large quantities of CA 125 in the normal female genital tract makes it worthwhile to study the functional properties of this antigen.

Human chorionic gonadotropin in early normal and pathologic pregnancy

Discordant levels in peripheral maternal blood and blood from the uterine and abdominal cavities

Johan Arnt Steier, M.D., Roar Sandvei, M.D., and Ole L. Myking, M.D.

Bergen, Norway

Human chorionic gonadotropin was assayed in 25 cases after first-trimester induced abortion, in 45 cases of spontaneous abortion in the first trimester, and in 27 cases of ectopic pregnancy. Blood was obtained from an antecubital vein and from the uterine cavity. In the cases of ectopic pregnancy blood was also obtained from the abdominal cavity. In the group of induced abortion the human chorionic gonadotropin levels in peripheral maternal blood did not differ significantly from the levels in the uterine cavity. In the groups of spontaneous abortion and ectopic pregnancy the human chorionic gonadotropin levels were significantly higher in blood from the uterine cavity and the abdominal cavity, respectively. In four cases (three with spontaneous abortion and one with an ectopic pregnancy) human chorionic gonadotropin was not detectable in peripheral maternal blood, while it was found in blood from the uterine and abdominal cavities. (AM J OBSTET GYNECOL 1986;154:1091-4.)

Key words: Human chorionic gonadotropin, ectopic pregnancy, spontaneous abortion, induced abortion

Human chorionic gonadotropin (hCG) is produced in large quantities by the syncytiotrophoblast. By use of sensitive radioimmunoassays it is detectable in peripheral maternal serum as early as 6 to 8 days after conception.[1] In early normal pregnancy the hCG levels rise rapidly, with a doubling time of 1.7 to 2 days, reaching a peak after 60 to 80 days.[2] In pathologic conditions such as ectopic pregnancy and spontaneous abortion the levels are found to be lower than in normal gestation of the same duration.[3] Some pathologic cases are on record in which no trace of hCG in peripheral blood was found, although histologic examination of the surgical specimens confirmed pregnancy. Devitalized trophoblast with no circulating hCG has been suggested as the most likely explanation.[4] We have observed pathologic pregnancies in which blood from the uterine cavity and blood from the peritoneal cavity have con-

1,130	1,410	17,800	39,400	Secretory endometrium

tained relatively high levels of hCG in the presence of low or no detectable levels in peripheral blood. This could mean that the trophoblast is still vital with continued production of hCG, in amounts too small for detection in peripheral blood. The discordant hCG values in serum specimens from different sources in the same patient were evaluated in this study.

Material and method

Three groups of women were examined. Relevant characteristics are listed in Table I.

The first group consisted of 25 patients admitted to the hospital for legal termination of uneventful first-trimester pregnancy, all terminated by vacuum suction followed by curettage. Blood samples were drawn simultaneously from an antecubital vein and from the uterine cavity after rupture of the membranes and partial removal of the pregnancy products.

The second group consisted of 45 patients admitted because of spontaneous abortion. All had vaginal bleeding and lower abdominal pain with dilatation of the cervical os. In no case did ultrasonography show an intact gestational sac. Forty-two patients had an incomplete abortion and three had a complete abortion. In 39 cases the removed tissue was examined histologically. In the remaining six macroscopic examination revealed undisputable pregnancy products. Blood samples were drawn simultaneously from an antecubital vein and from the uterus or vaginal vault during evacuation.

The third group consisted of 27 patients with ectopic pregnancy. In all cases the pregnancy was located in a fallopian tube, which was ruptured in 24 and not ruptured in three cases. The amount of intraperitoneal blood was measured, and the diagnosis was confirmed by histologic examination of the removed tubal tissue. In all cases blood samples were obtained simultaneously from the intraperitoneal cavity and an antecubital vein. In 13 cases blood samples were also obtained from the uterine cavity during curettage. In the three cases with nonruptured fallopian tubes blood was aspirated by puncture of the affected tube before removal of the pregnancy.

hCG was assayed in serum by an hCG β-subunit ra-

dioimmunoassay method without extraction. The technique is a modification of a method described by Vaitukaitis et al.,[5] which has been described in detail in a previous report.[6] The sensitivity of the method is 5 U/L of hCG.

Results

The diagnoses and the levels of hCG are shown in Fig. 1.

In the patients having induced abortion 14 had higher levels of hCG in the antecubital vein than in the uterine cavity, while 11 had slightly higher levels in blood from the uterine cavity.

Of the patients with spontaneous abortion 42 had significantly higher levels of hCG in blood from the uterine cavity than from the antecubital vein (2 $p < 0.0001$, Wilcoxon test for two samples). The approximate values can be read from Fig. 1. The three patients with complete abortion had no detectable hCG in antecubital vein blood and low values of hCG in blood from the uterine cavity, presented with connecting lines in Fig. 1. The findings in these three patients including the results of the histologic examination are listed in Table II.

In the group of women with ectopic pregnancy the amounts of intra-abdominal hemorrhage ranged between 20 and 1500 ml with a median volume of 100 ml. All 27 patients had significantly higher levels of hCG in blood from the intraperitoneal cavity than in blood from an antecubital vein (2 $p < 0.0001$). Of the 13 patients in whom blood was obtained from the uterine cavity, all had significantly higher levels of hCG in abdominal blood than in blood from the uterus (2 $p < 0.005$). Nine patients also had higher levels of hCG in uterine blood than in blood from the antecubital vein ($p < 0.005$). One patient had hCG amounts of <5, 363, and 276 U/L in antecubital venous blood, abdominal blood, and uterine blood, respectively. Table III gives the results of three patients with nonruptured fallopian tubes. All had much higher levels of hCG in the fallopian tube than in the other serum specimens.

Comment

The main portion of the hCG produced by the trophoblast is secreted into the maternal circulation.

The detection of hCG in peripheral maternal serum has been taken as evidence of vital trophoblast and, conversely, negative tests have been interpreted as indicating no pregnancy present. Quantitative measurements with sensitive radioimmunoassays have revealed lower levels of hCG in peripheral maternal serum in cases of pathologic pregnancies such as spontaneous abortions and ectopic pregnancies as compared with those of normal gestations of the same duration.[3]

The current results correlate well with this, but they also reveal a significant difference between the low levels of hCG in peripheral maternal blood and the higher levels in blood from the site of gestation in cases of pathologic pregnancies. This contrasts with the high values of hCG in blood from both the antecubital vein and the uterine cavity in normal pregnancies. It might also rule out a simple dilution effect in the maternal circulation as the only explanation of this discordance.

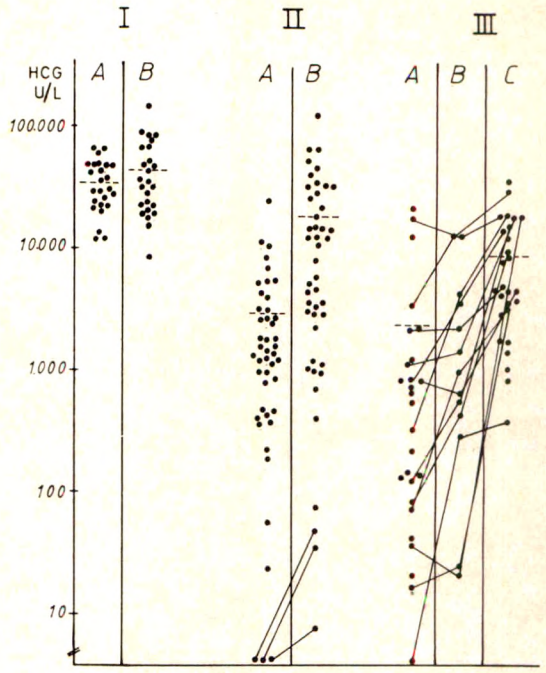

Fig. 1. The hCG levels in blood from an antecubital vein *(A)*, from the uterine cavity *(B)*, and from the abdominal cavity *(C)* in patients with induced abortion *(I)*, spontaneous abortion *(II)*, and ectopic pregnancy *(III)*. The connecting lines in group *II* represent the three patients with nondetectable hCG values in an antecubital vein and the corresponding hCG values in blood from the uterine cavity. In group *III* they represent the 13 patients in whom hCG was measured in the three specimens.

Sandvei et al.[4] found nondetectable levels of hCG in three of 100 cases of ectopic pregnancy with devitalized pregnancy tissue. In our study one patient with ectopic pregnancy and three with spontaneous abortions had no detectable hCG (<5 U/L) in peripheral maternal serum while still having positive values of hCG in blood from the uterine cavity (two patients) and abdominal cavity (three patients) (Table II).

The high levels of hCG in blood from the nonruptured fallopian tubes are not surprising, since the tubes are so near the site of production (Table III).

Earlier studies have revealed a long time until disappearance of hCG after termination of normal pregnancies and a much shorter time span after removal of ectopic pregnancies and spontaneous abortions as the result of a combination of factors including the pro-

duction and elimination of hCG.[6] In cases of ectopic pregnancy partial devitalization of the placenta is reported.[4] At least some devitalization of pregnancy tissue would also be expected in spontaneous abortions, and in both conditions this could result in less circulating hCG. Reduced blood flow and small functioning areas of the placenta could theoretically also involve qualitatively different secretory activity of the trophoblast, resulting in altered forms of the hCG molecule. In support of this theory a shorter plasma half-life and altered immunoreactivity produced by free subunits, peptide fragments, desialated or asialo hCG, and modified carbohydrate residues of hCG have been reported.[7-11]

Also a large molecular species which interacts with antisera to hCG, α-subunit hCG, and β-subunit hCG has been described.[12]

Another possibility for the discordant hCG values obtained could be the peripheral catabolism, which in addition to secretion might play an important role in regulating the serum level of biologically active hormone.[13]

The present findings raise questions that need further investigation, some of which concern the molecular basis of hCG. This involves the problem of different antibody specificity for different molecular forms of hCG.

As a practical conclusion, when a sensitive radioimmunoassay is used for detection of hCG, a negative test in peripheral maternal blood does not always exclude pregnancy. Blood obtained from the intraperitoneal cavity or from the vagina should also be examined for hCG as a further step to confirm or exclude pregnancy.

Factors related to the increasing cesarean section rates for cephalopelvic disproportion

Eliot L. Silbar, M.D.†
Highland Park, Illinois

At the Highland Park Hospital the increase in cesarean section rates has paralleled the national increase. Data from cesarean deliveries performed for cephalopelvic disproportion (a leading reason for cesarean section) in 1969 to 1972 (group 1) and 1979 to 1982 (group 2) were evaluated to determine maternal, fetal, and delivery factors that might be related to the increase in the rates. The data suggested that the more frequent diagnosis of cephalopelvic disproportion and the increased size of the group 2 infants were the primary reasons for the increase in cesarean section rate. This increased rate was paralleled by a decline in forceps-assisted delivery and in perinatal mortality rates. (AM J OBSTET GYNECOL 1986; 154:1095-8.)

Key words: Cesarean section, cephalopelvic disproportion, fetal weight

During the past 20 years considerable change has occurred in obstetric practice. The widespread use of electronic intrapartum and prenatal fetal monitoring and the use of other surveillance methods to assess fetal well-being have been paralleled by an increase in cesarean section rates. Numerous studies have been undertaken to evaluate factors associated with the increasing cesarean section rates. In 1980, a National Institutes of Health Consensus Development Conference was held to address issues related to cesarean childbirth.[1] At this conference it was reported that in the United States the cesarean section birth rate per 100 births increased from 5.7 in 1970 to 14.7 in 1978. Dystocia was found to be one of the leading indications for cesarean section and contributed to 30% of the increase in the cesarean section rates from 1970 to 1978.

At the Highland Park Hospital the increase in cesarean section rates is similar to the national increase. The cesarean section rate increased from 5.4 per 100 deliveries in 1969 to 1972 to 13.1 per 100 deliveries in 1979 to 1982. At the same time there was a significant decrease in the proportion of forceps-assisted deliveries, from 25.6 per 100 deliveries in 1969 to 1972 to 6.3 per 100 deliveries in 1979 to 1982 (Table I). It is my hypothesis that the increase in cesarean section rates during the 10-year period is due primarily to the more frequent diagnosis of cephalopelvic disproportion as an indication for cesarean section. In these cases, attempts at difficult midforceps vaginal deliveries might compromise the infants, and cesarean sections are more frequently performed.

The purpose of the present article is to evaluate factors that might be associated with the increasing rate of cesarean sections for women with cephalopelvic disproportion who were delivered of their infants at the Highland Park Hospital.

Material and methods

The Highland Park Hospital is a private community hospital in north suburban Chicago. In recent years about 900 deliveries a year have been performed at the hospital. To evaluate factors that might have contributed to the rising cesarean section rate for cephalopelvic disproportion, the medical records of women who were delivered of their infants by cesarean section in 1969 to 1972 and in 1979 to 1982 were identified. These medical records were reviewed to identify women who had cesarean sections performed for indications in the cephalopelvic disproportion spectrum. A total of 186 women were identified, 48 who were delivered in 1969 to 1972 (group 1) and 138 who were delivered in 1979 to 1982 (group 2). Excluded from both groups were multiple gestations, deliveries of infants who weighed <1500 gm at birth, and women with indications for cesarean section other than cephalopelvic disproportion. Lumbar epidural analgesics and anesthetics were not used in either group. There was no significant difference in the pattern of analgesics or anesthetics between the two groups.

The following data were abstracted from the medical records of group 1 and 2 subjects: maternal demographic characteristics, maternal weight gain, maximum dilatation reached before delivery, time from maximum dilatation to delivery, maximum station

reached, persistent occipitoposterior position, time of day of delivery, use of Pitocin, 1- and 5-minute Apgar scores and fetal weight. A woman's weight gain was determined as the difference between weight at hospital admission and weight at the time pregnancy was diagnosed. These data were analyzed to evaluate differences between maternal characteristics, events relating to labor, and fetal factors in group 1 and 2 subjects that might relate to the increased cesarean section rate. The data were analyzed by use of standard statistical methods for continuous and categorical data. In the text, only the p values (significance levels) associated with the tests are given.

Results

Similar ($p > 0.10$) proportions (about 29%) of subjects who underwent cesarean section in 1969 to 1972 and 1979 to 1982 were diagnosed as having cephalopelvic disproportion (Table II). However, when considered as a proportion of deliveries there was a significant increase ($p < 0.01$) from 1969 to 1972 to 1979 to 1982 in the percentage of subjects with cephalopelvic disproportion who had cesarean sections.

Maternal factors. Maternal factors for group 1 and 2 subjects are given in Table III. Compared with the group 1 subjects, the group 2 subjects were older ($p < 0.05$) and gained more weight during pregnancy.

Factors related to delivery. The maximum cervical dilatation achieved before cesarean section was greater for group 2 than for group 1 subjects ($p < 0.05$) (Table IV). The mean time at the maximum cervical dilatation achieved was about 30 minutes longer for the group 2 subjects (3.0 versus 2.5 hours). Also the maximum station of fetal head descent was greater ($p < 0.05$) for the group 2 subjects. In group 1 the fetal head did not engage the vertex in 46% of the subjects. The corresponding rate for the group 2 subjects was 30%. The rates of Pitocin augmentation were similar ($p > 0.10$) for the two groups (group 1, 27%; group 2, 28%). The rates of persistent occipitoposterior presentations were similar ($p > 0.10$) for groups 1 and 2 (31% versus 22%).

The time of day when cesarean section was performed was evaluated to determine if there were particular periods during the day when the procedures were more likely to be performed. For group 1 subjects, the procedures were uniformly distributed throughout the day. For group 2 subjects, there was a decrease ($p < 0.05$) in the number of procedures performed from midnight to 4 AM compared with 8 PM to midnight.

Fetal factors. The average 1- and 5-minute Apgar scores were similar ($p > 0.10$) for the two groups (group 1, 9 and 10; group 2, 8 and 9). One infant (2%) in group 1 and nine infants (7%) in group 2 had 1-minute Apgar scores of <7 ($p > 0.10$). All 5-minute Apgar scores were ≥7.

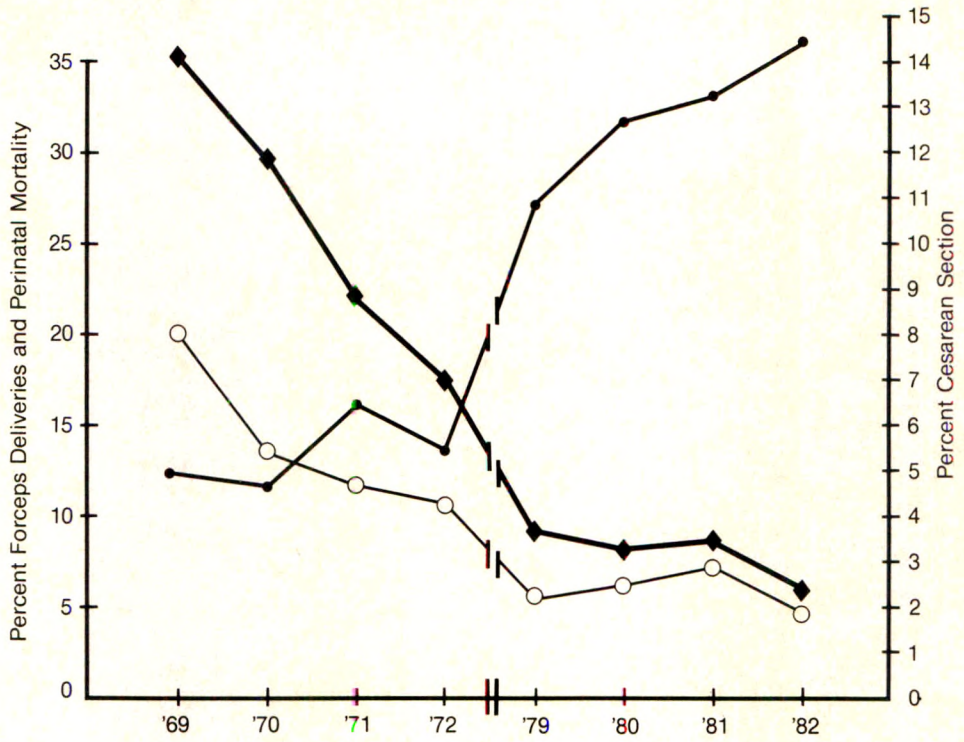

Fig. 1. Comparison of perinatal mortality rates, forceps-assisted delivery rates, and cesarean section rates, 1969 to 1972 and 1979 to 1982. ♦, Forceps rate; ●, cesarean section rate; ○, perinatal mortality rate.

There were too few perinatal deaths in groups 1 and 2 for reliable assessment of perinatal mortality rates. For all deliveries, the perinatal mortality rates (per 1000 deliveries) decreased from 14 in 1969 to 1972 to seven in 1979 to 1982. This reduction in the perinatal mortality rates was paralleled by a decrease in the rate of forceps-assisted deliveries and an increase in the cesarean section rate (Fig. 1).

The mean birth weight of group 2 infants (3772 gm) was significantly higher ($p > 0.05$) when compared with the mean birth weight of group 1 infants (3486 gm). However, the mean birth weights of infants were delivered vaginally during the same time periods (1969 to 1972 and 1979 to 1982) were similar ($p > 0.10$) (3402 versus 3430 gm). The mean birth weights of all infants born at the Highland Park Hospital during the two time periods were 3430 and 3570 gm, respectively. The corresponding birth weights for all infants born in the United States in 1972 and 1982 were 3300 and 3363 gm (United States Bureau of Statistics).

Comment

Although there were some differences between the group 1 and 2 subjects and factors related to their deliveries, none of the factors evaluated, considered either individually or as a group, explained the higher cesarean section rate for deliveries in 1979 to 1982 compared with 1969 to 1972. In fact, the data suggest that the group 1 patients were more aggressively managed (shorter second stage of labor, less cervical dilatation at the time of cesarean section) than the group 2 patients. The data show that a more cautious attitude was taken by obstetricians in later years toward performing cesarean section for cephalopelvic disproportion. The only fetal factor evaluated that could explain the higher cesarean section rate for the group 2 subjects was their greater average weight.

The larger infants of the group 2 mothers may be related to the greater weight gain of their mothers. The recent practice of discouraging women from smoking during pregnancy and improved nutrition could also account for the larger infants. However, no data on parental smoking habits or maternal nutrition were available for evaluation. Since the differences in the mean birth weights of all infants (at Highland Park Hospital and in the United States) and those delivered vaginally during 1969 to 1972 and 1979 to 1982 were small, it is reasonable to assume that none of the differences between the group 1 and group 2 subjects accounted for the greater weight of the infants of group 2 mothers. The most likely explanation for the increased cesarean section rates is that cephalopelvic disproportion was diagnosed with increased frequency as an indication for cesarean section.

Hughey et al.,[2] in 1977, suggested that the increased cesarean section rate due to dystocia was a result of

increased birth weight. These investigators noted that the average birth weight increased by 100 gm during a 6- to 8-year period when cesarean section rates were increasing. Data from New York[1] have shown the increased rate of cesarean sections to be similar across birth weights. However, data that gave the cesarean section rates for different indications across weight classes were not provided. Without these data, one cannot discount the hypothesis that the increased cesarean section rate is due primarily to the more frequent diagnosis of cephalopelvic disproportion and secondarily to the larger infants. Further study of this issue is required. If part of the increased rate of cesarean section is due to the increased frequency of diagnosis of cephalopelvic disproportion, then this part of the increased rate is justified. It may lead to lower perinatal mortality rates and fewer complications in the infants.

Effects of maternal transport on admission patterns at a tertiary care center

Richard M. Cowett, M.D., Donald R. Coustan, M.D., and William Oh, M.D.
Providence, Rhode Island

Major changes have occurred in the delivery of perinatal care during the last two decades. Documentation of perinatal regionalization statistics at Women and Infants Hospital of Rhode Island in Providence support (1) the increasing proportion of low birth weight infants in the region being born at the tertiary care center, (2) the decreasing number of neonatal transports in concert with an increasing number of maternal transports, and (3) the increasing proportion of neonatal transports with birth weights ≥2500 gm. Patterns of modern perinatal care are materially changing the delivery of health care at tertiary care facilities. (Am J Obstet Gynecol 1986;154:1098-100.)

Key words: Perinatal regionalization, maternal transports, neonatal transports

During the past two decades, major changes have occurred in the delivery of perinatal care. Since the advent of perinatal regionalization,[1] there has been a trend of neonatal transports from community hospitals to tertiary centers associated with significant decreases in neonatal morbidity and mortality rates.[2, 3] During the past decade increasing numbers of maternal transports have also been reported.[3] The latter may affect utilization patterns at tertiary care centers. We speculated that as the maternal transport rate rose, the neonatal transport rate would fall, since mothers with high-risk pregnancies would have been transported antenatally and would be delivered at the tertiary care center. We tested this hypothesis with the use of data obtained from our region. These observations are relevant in the planning and budgeting processes of perinatal facilities.

Material and methods

Women and Infants Hospital of Rhode Island (WIHRI) is a private, university-affiliated hospital serving as the perinatal tertiary care facility for Rhode Island and southeastern Massachusetts. The hospital is the only tertiary care facility between Boston, Massachusetts (75 miles northeast), and New Haven, Connecticut (100 miles southwest).

There are eight primary care obstetric facilities in the state of Rhode Island in addition to WIHRI, each having between 300 and 1800 deliveries per year. WIHRI delivers between 40% and 60% of the state's 14,000 live births per year. In Southeast Massachusetts, there are

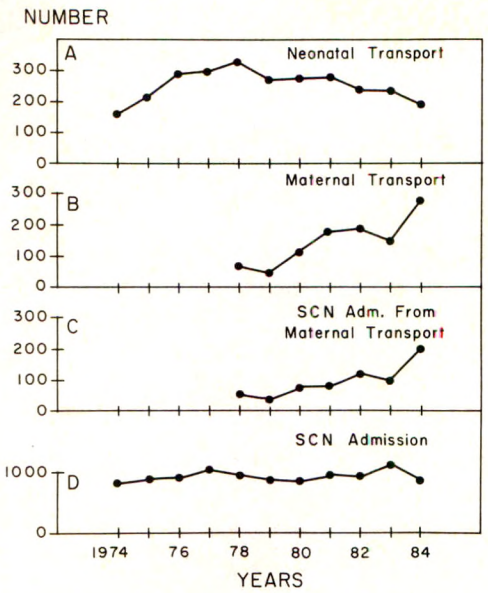

Fig. 1. *A*, Total number of neonatal transports per year since 1974. *B*, Total number of maternal transports per year since 1978. *C*, Total number of infants per year who were admitted to the special care nursery, who were born to mothers who were transported, since 1978. *D*, Total number of admissions per year to the special care nursery since 1974.

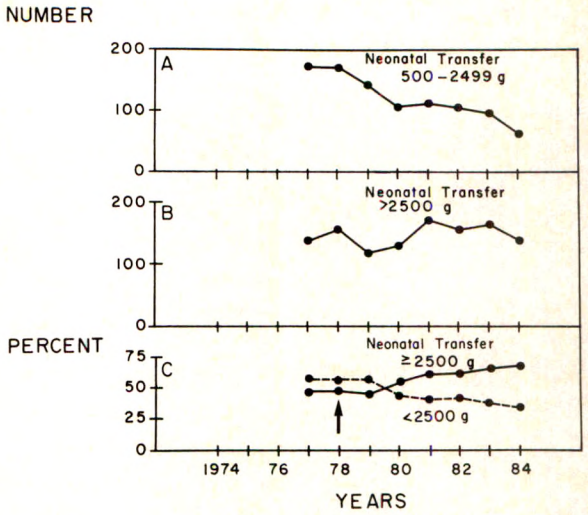

Fig. 2. *A*, Total number of neonatal transports per year, >500 and ≤2499 gm, since 1977. *B*, Total number of neonatal transports per year, ≥2500 gm, since 1977. *C*, Percentage of infants <2500 and ≥2500 gm who were neonatal transports per year since 1977. The *arrow* at the bottom denotes the year formal maternal transfer analysis began.

five obstetric facilities delivering a total of 6000 babies per year, none of which is a tertiary care center. Thus WIHRI is the only tertiary care center for the 13 hospitals within the region, with 20,000 live births per year.

WIHRI began its tertiary care center operation in 1974, with the establishment of a special care nursery, along with a neonatal transport team. In 1978, the maternal-fetal medicine program was added with strong emphasis on maternal transport in high-risk pregnancy. We define maternal transports as those pregnant women who originally elected to be delivered in hospitals within the region, but who, because of complications, were transported to WIHRI, usually by decision of the primary care obstetricians. No specific records were kept on the mode of transport. Some patients came by ambulance as would be common if the patient was in labor, and others by self-transport if labor was not imminent.

To evaluate the effects of an increasing number of maternal transports on the patterns of admission at a tertiary care facility, the following data were collected from annual hospital statistics: live births, neonatal and maternal transports, the number of special care nursery admissions of infants who were born to women who were transported antenatally, and total admissions to the special care nursery. The data were subdivided into two birth weight categories: >2500 and ≤2500 gm. For the maternal transports, the data are available only since 1978. There were some maternal transports before 1978 but the number was small, and complete data are not available.

Statistical analysis was by χ^2.

Results

From 1973 through 1984, there was an increase in live births at WIHRI, from 5300 in 1973 to 7317 in 1984. The number of low birth weight infants (≤2499 gm) born at WIHRI also increased. In 1973, 6.7% of the live births were low birth weight; by 1984, this had increased to 8.7% ($p < 0.001$ by χ^2 analysis).

Fig. 1 shows a gradual increase of infants transported to WIHRI during the period between 1974 and 1978 (154 in 1974 to 333 in 1978). From 1978 through 1984, there was a gradual decline from 333 to 198. During the same period of time, maternal transports increased from 65 in 1978 to 280 in 1984. Correspondingly the numbers of infants admitted to the special care nursery who were born to women transported to WIHRI increased from 43 in 1978 to 201 in 1984. During this time period the total number of admissions to the special care nursery remained stable at around 950 to 1000 per year.

Fig. 2 depicts the actual number of neonatal transports by birth weight: low birth weight (>500 and ≤2499 gm) and term (>2500 gm) infants. The number of low birth weight infants transported decreased over the years. In contrast, the number of term infants transported remained unchanged. Thus the percentage of term infants transported to our facility increased from 44.6 to 67.2 between 1977 and 1984 ($p < 0.001$).

Comment

The purpose of this report is to document how the patterns of modern perinatal care affect delivery of health care at a tertiary care facility. There are several reports of improvement in perinatal mortality and morbidity as a result of perinatal regionalization.[3-5] What has not been evaluated is the effect of regionalization on admission and utilization patterns in a tertiary care center.

The rise in the number of live births in the tertiary care center from 1974 to 1984 is partly due to an increase in the number of births of low birth weight infants. This is to be expected because of heightened awareness on the part of primary care physicians of the most beneficial location for the delivery of the high-risk infant. Furthermore, the establishment of the subspecialty of maternal-fetal medicine and the availability of perinatologists in the tertiary care center has also stimulated increased maternal transports. With the increased number of preterm pregnant women being transported to the tertiary care center, the percentage of low birth weight infants increased accordingly. The continuation of comparable numbers of term infants being transported to the tertiary care center reflected a phenomenon that was not unexpected: While the primary care physicians readily recognized the imminent high-risk potential of a preterm pregnancy (thus referring the mother to a tertiary care center), there was less accuracy in identification of the high-risk term pregnancy whose infant would require referral. The latter accounts for the increased percentage of term infants in the neonatal transport statistics.

From the administrative and fiscal perspective, it has become apparent that establishment of a maternal-fetal medicine program in a tertiary care center may require commitment of additional resources to this component when statistics indicate a trend toward more maternal transports. At the same time, allocation of fiscal resources to the neonatal program should remain unchanged despite a fall in the number of neonatal transports since the total number of nursery days would remain unchanged. Since total admissions to the special care nursery are constant, there is a need for allocation of resources within a community or region to the tertiary care center for delivery of the appropriate level of care.

Septic shock with renal failure after chorionic villus sampling

Alicia I. Barela, M.D., Gary E. Kleinman, M.D., Ira M. Golditch, M.D., David J. Menke, M.D., W. Allen Hogge, M.D., and Mitchell S. Golbus, M.D.

San Francisco, California

A report of septic shock and renal failure after a chorionic villus sampling is presented. Uterine evacuation, antibiotics, and vasopressor therapy were unsuccessful in reversing hypotension, coagulopathy, and anuria. The patient's condition improved only after exploratory laparotomy and removal of the uterus, ovaries, and fallopian tubes. The incidence of such serious complications must be determined. (Am J Obstet Gynecol 1986;154:1100-2.)

Chorionic villus sampling has recently become available for the prenatal diagnosis of genetic disorders in the first trimester of pregnancy. The question of safety of the procedure has been raised, but no serious maternal complications have been reported. The following is a case report of a patient transferred to the Kaiser Foundation Hospital in San Francisco, California, for acute dialysis after chorionic villus sampling complicated by septic shock, disseminated intravascular coagulation, and anuria.

Case report

A 34-year-old, gravida 2, para 0 woman underwent chorionic villus sampling at 11½ weeks' gestation. Cultures for gonococci and chlamydia were both negative before the procedure. The procedure required two catheter insertions and was without incident. Four days later the patient presented to the emergency room complaining of fever and vaginal spotting. There was no history of self-instrumentation. Pelvic examination revealed a nontender uterus consistent with 10 to 12 weeks' gestation. Temperature was 37° C and the leukocyte count was 8900/mm³. The patient was diagnosed as having the "flu" and sent home with instructions to return if she developed higher temperatures. She returned 6 hours later with shaking chills and a temperature of 38.9° C. Pelvic examination again revealed a nontender uterus and no masses. The patient was admitted for intravenous hydration and observation.

At the time of admission, the leukocyte count had decreased to 3500/mm³ with 38% segmented cells and 57% band cells noted. Five hours after admission pelvic examination revealed marked uterine tenderness, and a diagnosis of septic abortion was made. She was begun on a regimen of intravenous cefoxitin, 2 gm every 6 hours, and gentamicin, 80 mg every 8 hours, and shortly thereafter a suction curettage was performed while she was under general anesthesia. After evacuation of the uterus the temperature rose to 40° C and blood pressure dropped to 60/30 torr. The leukocyte count decreased further to 1000/mm³ and clotting studies were consistent with a severe coagulopathy (platelets, 20,000/mm³; partial prothrombin time, >150 seconds; fibrinogen, <50 mg/100 ml). Clindamycin, 900 mg every 8 hours, was added to the antibiotic regimen. A dopamine hydrochloride infusion was begun and she was transferred to the intensive care unit.

Examination at this time revealed marked peripheral edema, bibasilar pulmonary rales, and abdominal tenderness and guarding. There was a small amount of bleeding from the vagina, the cervical os was closed, and the uterus was not palpable secondary to guarding. Ecchymosis and bleeding were noted from the venipuncture sites. A Swan-Ganz catheter was placed with a pulmonary wedge pressure of 24 torr. Urine output dropped to 28 ml for a 4-hour period with no response to increasing doses of furosemide. Creatinine levels increased progressively to 2.9 mg/100 ml. The patient received 20 units of platelets, two units of packed red blood cells, and four units of fresh-frozen plasma with no improvement in the clotting studies. She was then transferred to Kaiser Permanente Medical Center, San Francisco, California, for immediate dialysis.

Immediately after arrival a Scribner arteriovenous shunt was placed for hemodialysis. Gentamicin was discontinued because of worsening renal function, but cefoxitin and clindamycin were continued. The next day the patient was afebrile but there was no improvement of the disseminated intravascular coagulation. A dopamine infusion (20 μg/kg/min) was required to maintain a blood pressure of 90/60 torr. On pelvic examination the cervical os was noted to be closed, the lochia minimal and not foul, and there was no cervical motion tenderness. Diffuse abdominal tenderness and guarding continued. Ultrasound examination of the uterus was consistent with either residual blood clots or retained products of conception. Because there was no improvement in blood pressure or coagulation status, a repeat uterine evacuation was performed with removal of retained fetal skeletal parts.

The hemodynamic and coagulation status of the patient did not improve during the 20 hours after the repeat uterine evacuation. Because the tenuous status of the patient persisted, total abdominal hysterectomy and bilateral salpingo-oophorectomy were carried out with the patient under general anesthesia.

At the termination of the operation, vasopressor therapy was no longer necessary to maintain normal blood pressure. Clotting parameters improved after operation and were normal within 24 hours. The pulmonary function improved rapidly during the next 48 hours.

Blood cultures from the initial emergency room visit were reported positive for *Peptostreptococcus*, probable *Peptococcus*, and a gram-negative anaerobe. All subsequent cultures were negative. The patient was continued on a regimen of clindamycin for a total of 14 days. Anuria persisted after operation until the day before discharge, when she voided 150 ml of urine. She was discharged home on hospital day 19 to be followed up with outpatient hemodialysis three times weekly. Two weeks after discharge, dialysis was no longer required.

Pathologic examination of the uterus revealed endometritis, myometritis, and fibrin thrombi containing trophoblasts within the myometrium. No pathologic abnormalities were noted in the ovaries and tubes.

Comment

Chorionic villus sampling was recently introduced in this country as a technique for early prenatal diagnosis. Its popularity has increased rapidly. Because chorionic villi can be obtained directly by transcervical aspiration in the first trimester of pregnancy, fetal cells can be analyzed for chromosomal and biochemical defects immediately. Amniocentesis, by contrast, is not performed before the sixteenth week of gestation and results are not available for an additional 2 to 3 weeks until the fetal cells are grown in tissue culture and analyzed.

Thus chorionic villus sampling offers patients the psychological advantage of knowing if they have an affected offspring at an earlier stage of gestation. If a woman chooses to terminate her pregnancy, a first-trimester abortion is safer, less costly, and more acceptable psychologically.

Although an attractive alternative, chorionic villus sampling has potential risks. Infection, rupture of the fetal membranes, spotting, frank bleeding from the sampling site, dissection of the chorion frondosum, and a rate of fetal loss greater than that seen with amniocentesis have all been reported.[1] A careful search of the literature, however, failed to reveal any reports of serious maternal complications, including septic shock.

Spotting appears to be a common complication, usually not associated with long-term sequelae.[1] Our patient presented with spotting and fever; she had no abdominal pain or pelvic tenderness. When it became apparent that infection was present, antibiotics were started and uterine evacuation was carried out. After a second dilatation and evacuation procedure yielded retained fetal parts, there was hope that she would begin to improve because an obvious nidus for infection had been removed. Conservative management of septic shock and renal failure in patients with septic abortions has been advocated by Hawkins et al.[2] in order to preserve fertility. Our patient, although stable on a regimen of therapeutic doses of antibiotics, pressor therapy, and hemodialysis, did not improve during 20 hours after a second uterine evacuation; it became necessary to proceed with an exploratory laparotomy, a total hysterectomy, and a bilateral salpingo-oophorectomy.

The seriousness of this complication after chorionic villus sampling raises the question of safety of the procedure. Clearly the frequency of serious complications must be determined. The unfortunate outcome in this case has led us to propose the following recommendations: (1) continued presampling screening and treatment of existing infection; (2) use of strict aseptic technique; (3) limitation of the number of catheter insertions and use of a new catheter for each sampling attempt; (4) inclusion in the consent form under the statement of risks, "possible serious infection requiring surgical intervention"; (5) counseling of all patients to abstain from sexual intercourse for a period of several days after the procedure.

Relationship of baseline fetal heart rate to gestational age and fetal sex

Maurice L. Druzin, M.D., J. Milton Hutson, M.D., and Terri G. Edersheim, M.D.
New York, New York

A study of 37 patients who underwent 365 antepartum fetal heart rate tests showed a significant difference in heart rate between 19 to 24 weeks' and 36 to 40 weeks' gestation. Baseline heart rate remained within the normal range, suggesting that an abnormal heart rate at any gestational age should prompt further fetal assessment. Baseline fetal heart rate was not significantly different between male and female fetuses.
(Am J Obstet Gynecol 1986;154:1102-3.)

Key words: Baseline fetal heart rate, gestational age, fetal sex

Baseline fetal heart rate has long been used as an indication of fetal status. The currently acceptable range of a normal baseline fetal heart rate is 120 to 160 bpm, with >160 bpm designated as "tachycardia" and <120 bpm as "bradycardia."[1, 2]

The most common cause of baseline tachycardia is maternal-fetal fever, with chronic hypoxemia as the more ominous cause in other instances. Fetal tachyarrhythmias and maternal thyrotoxicosis are rare causes of tachycardia. Prematurity, with apparent "immaturity" of the autonomic nervous system, has long been

Table I. Mean baseline fetal heart rate

Fetuses	*Estimated gestational age*				
	19-24 wk	*24-28 wk*	*28-32 wk*	*32-36 wk*	*36-40 wk*
Male	143 ± 8	143 ± 6	136 ± 8	134 ± 14	131 ± 8
Female	144 ± 4	143 ± 6	139 ± 6	138 ± 6	133 ± 8
Total	143 ± 7*	143 ± 6	137 ± 7	136 ± 7	132 ± 8*

*$p < 0.01$.

thought to be related to physiologic tachycardia. Causes of fetal bradycardia include acute hypoxia, congenital heart lesions, and congenital heart block.[1, 2] There is also a popularly held view that baseline fetal heart rate may be an indicator of fetal sex.

This study was undertaken to determine the antepartum baseline fetal heart rate in a group of patients who subsequently had normal pregnancy outcomes.

Material and methods

Thirty-seven patients underwent 365 antepartum fetal heart rate tests at 19 to 40 weeks' gestation. Indications for testing included prematurity in six cases, gestational diabetes in five, collagen vascular disease in three, and miscellaneous in seven. Eleven low-risk patients volunteered as controls for the study. Baseline fetal heart rate was defined as the average baseline fetal heart rate in a 10-minute period, rounded off to the nearest 5 bpm. All neonates were appropriate for gestational age; nine were delivered at ≤36 weeks. Five-minute Apgar scores were all ≥8. There were no congenital anomalies. There were 25 male and 12 female singleton births. None of the patients had thyrotoxicosis, and no fetal arrhythmias were detected.

Results

There was a statistically significant difference in baseline fetal heart rate between 19 to 24 weeks' and 36 to 40 weeks' gestation; there was no difference in baseline fetal heart rate between male and female fetuses at any gestational age (Table I).

Comment

While the difference in baseline fetal heart rate between 19 to 24 weeks' and 36 to 40 weeks' gestation was statistically significant, baseline fetal heart rate was never outside the "normal range" of 120 to 160 bpm. Maturation of the autonomic nervous system may account for the difference between the early and the late gestational age groups. The presence of abnormal fetal heart rate at any gestational age merits further investigation. Fetal sex has no influence on baseline fetal heart rate.

Relaxin and the radiolucent fissure in the symphysis pubis during pregnancy: The gas phenomenon

Mortimer R. Camiel, M.D.
Brooklyn, New York

A vertical radiolucent fissure is frequently seen in the symphysis pubis on x-ray pelvimetry studies. This phenomenon is illustrated and discussed. It appears to be a parameter of targeted relaxin softening and stretching of the symphysis. (Am J Obstet Gynecol 1986;154:1104-5.)

Key words: Relaxin, pubic symphysis gas phenomenon, pregnancy

Relaxin activity during pregnancy is associated with loosening, widening, and increased flexibility of the symphysis pubis. Late in pregnancy or during parturition, associated with such softening is a vertical fissure within the symphysis, which is frequently seen on the x-ray film as a dark streak of gas (Fig. 1).

Previous radiologic studies of this phenomenon, now contraindicated, confirm this targeted hormonal response of the symphysis to pregnancy. I searched for this finding in 100 unselected x-ray pelvimetry films obtained late in pregnancy.[1] All of the cases were of cephalic presentations. With the use of strict criteria and after the elimination of doubtful and even probably positive films, this finding was evident in 30 of the 100 cases. To test whether cephalic presentation affected the results, 22 unselected breech presentations were studied. Six of these (31.3%) were positive, the similarity of results suggesting a hormonal relationship. Parity, pelvic size, and pelvic shape did not play a significant role. Pain was infrequent. Williams[2] studied the x-ray pelvimetry results of 116 primigravid women and 116 multigravid women. The streak was detected in 41.5% of the patients, with no essential difference between the two groups. Age played no part. While the phenomenon was most common in late pregnancy or during parturition, on occasion, it was noted during the first or second trimester. In most instances the gas shadow disappeared within a week after delivery. In neither study was the outcome of labor deleteriously affected by the phenomenon.[1, 2]

Normally the symphysis is resistant to separation. It contains a compressed central fissure, unlined by synovial membrane, which is not visible on an x-ray film.

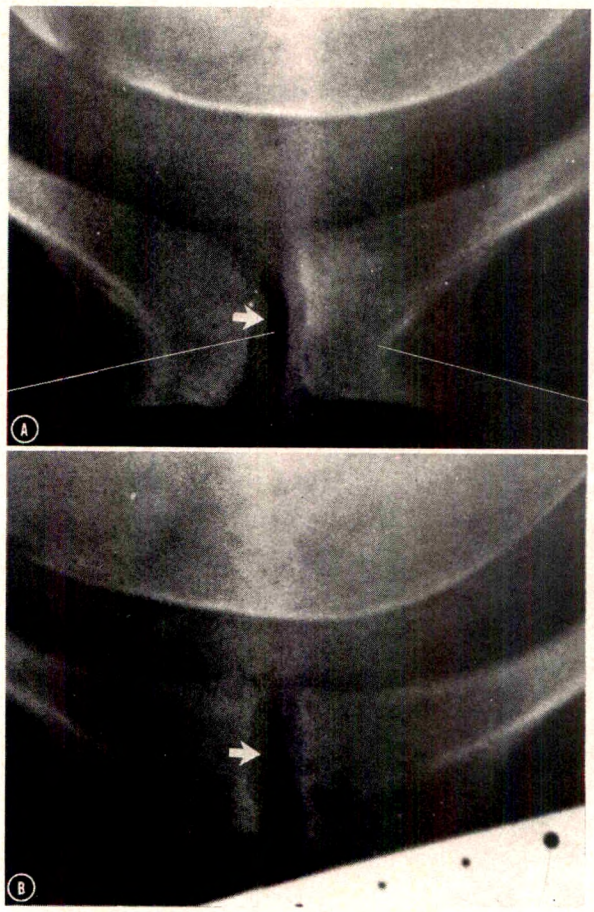

Fig. 1. *A* and *B*, Two examples of gas in the pubic symphysis during pregnancy.

This potential space may become real under the changes described with pregnancy. A negative pressure balance is created, followed by transmission of gas to fill the vacuum. Rarely, the visible cleft has been described with trauma and degenerative disease, but essentially it is a phenomenon of pregnancy. Occasionally the clefts are multiple or associated with tiny avulsions from the contiguous cortex, suggesting small components of

trauma and/or multiple anatomic clefts. Williams[2] found that with successive pregnancies the shadows tended to be the same, favoring an anatomic basis.

Relaxin has been detected in the nonpregnant state and even in men, but its greatest concentrations normally arise from the corpus luteum of pregnancy. It changes the biochemical nature of the cartilagenous connective tissue of the symphysis, resulting in its softening and increased flexibility. The radiologic visibility of the fissure is a parameter of such softening and stretching. When detected, it had no known harmful effect on the outcome of delivery. Indeed, as a component of pubic laxity, it probably reflects a useful concomitant of pregnancy. Its full implications will not be understood until the precise role of relaxin and its complex relationships to the other hormones of pregnancy are elucidated. Although this phenomenon has been described previously, this is the first report relating it to relaxin.

Assistance given by Ms. Mary Doherty, research librarian, and Philip Mullan, Department of Medical Illustration, is acknowledged with thanks.

Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization

John W. Seeds, M.D., and Watson A. Bowes, Jr., M.D.
Chapel Hill, North Carolina

The successful use of ultrasound-guided fetal umbilical venipuncture and direct intravascular transfusion in a case of severe hydrops fetalis at 28 weeks' gestational age is described. Complete reversal of the hydropic changes was observed in utero. The use of this new technique in fetal treatment of Rh disease is discussed. (Am J Obstet Gynecol 1986;154:1105-7.)

Key words: Hydrops fetalis, ultrasound, transfusion, antenatal

Direct intravascular fetal blood transfusion in the fetus severely affected by Rh immunization has been reported with the use of fetoscopy,[1] ultrasonically guided umbilical venipuncture,[2] and guided cannulation of the umbilical vein within the fetal liver.[3]

Reported here is a case of severe hydrops fetalis at 28 weeks' gestation treated with a combination of intravascular and intraperitoneal transfusions. Complete reversal of the hydropic condition in utero was observed.

Case report

The patient, a 32-year-old woman, gravida 2, para 2-0-0-2, was referred to North Carolina Memorial Hospital at 28 weeks' gestation because of Rh immunization (anti-D). Sonography before referral showed severe hydrops fetalis. Amniocentesis was performed and the amniotic fluid optical density shift at 450 nm was reported to be 0.495.

Repeat ultrasound examination on arrival confirmed the presence of massive fetal ascites (Fig. 1), and moderate skin edema. No pleural or pericardial effusions were present. The placental thickness was 8.2 cm. Because of the severity of the condition, ultrasound-guided venipuncture and direct transfusion were undertaken.

The umbilical insertion on the placenta was identified, and a likely venipuncture site was chosen (Fig. 2). With the patient under parenteral sedation and local anesthesia, a 19-gauge needle catheter was placed percutaneously into the amniotic cavity, and the needle trocar was removed. A 21-gauge transfusion needle 18 cm long with a 26-gauge tip[1] was inserted through the cannula into the amniotic cavity and advanced under ultrasonic guidance to the umbilical vein. The umbilical vein was punctured and fetal blood aspirated. The fetal hematocrit was 14%, the fetal Po_2 was 20 mm Hg, and the Pco_2 was 45 mm Hg. An isovolumetric exchange was begun in 5 ml increments with the use of 90%

Fig. 1. This transverse midabdominal view of the fetus demonstrates the lower liver mass surrounded by ascitic fluid *(black area)*.

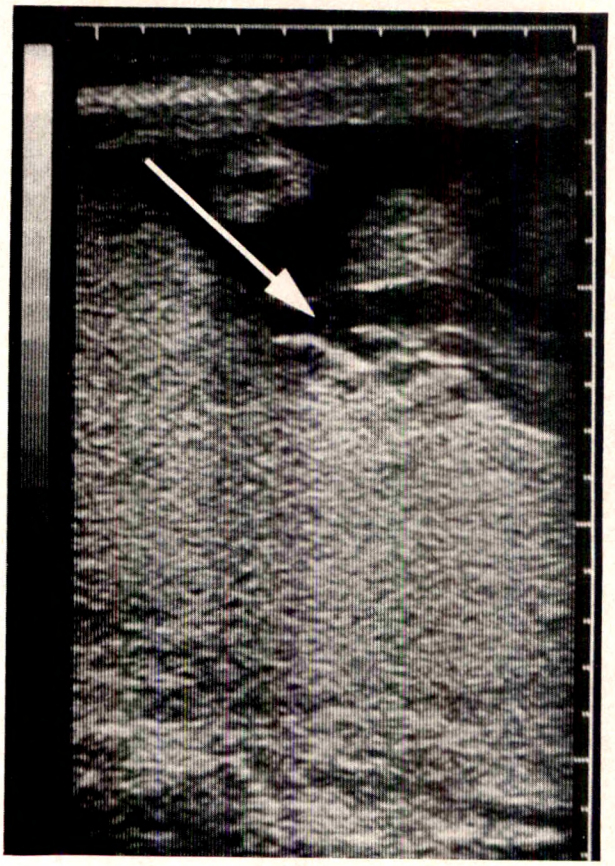

Fig. 2. This transverse sonogram of the upper right uterine fundus demonstrates the posterior placenta with the umbilical vein insertion. The *arrow* indicates the umbilical vein on the surface of the placenta and duplicates the approach used for umbilical venipuncture under ultrasound guidance.

packed, washed, irradiated, type 0, Rh-negative red blood cells to a total of 29 ml, after which aspiration was no longer possible. An additional 55 ml of cells was then slowly infused. No bleeding was apparent after needle removal. A 16-gauge Touhy needle was then inserted into the fetal peritoneal cavity and 200 ml of clear, yellow fetal ascitic fluid was removed. Eighty milliliters of donor red blood cells was infused into the peritoneal cavity. The fetal heart rate remained stable throughout these procedures.

One week after the transfusion, placental thickness was 7.1 cm. Two weeks later, fetal skin edema was gone, and by 3 weeks after transfusion there was no free fetal peritoneal fluid visible on ultrasound. One additional intraperitoneal transfusion of 110 ml of 90% packed cells was performed at 31½ weeks' gestation without complication.

Ultrasound at 34½ weeks showed no signs of hydrops. Amniocentesis was performed and the lecithin-sphingomyelin ratio was found to be 2.2. Delivery was by repeat cesarean section at 35 weeks, and the 2480 gm female infant had Apgar scores of 8 and 9 at 1 and 5 minutes. There were no signs of hydrops. The central neonatal hematocrit was 42% and only two fetal cells per 10,000 were seen with Kleihauer-Betke testing of cord blood. The neonate experienced mild transient tachypnea but required no exchange transfusion and was discharged with the mother.

Comment

Rodeck et al.[1] documented the potential utility of intravascular fetal transfusions by means of fetoscopy in early pregnancy. Fetoscopy was not considered here as it requires the intrauterine intrusion of a larger instrument, and intra-amniotic visibility is severely limited at 28 weeks' gestation by turbidity.

Ch. de Crespigny et al.[3] recently reported 16 direct transfusions in four cases with the use of a 20-gauge needle placed into the umbilical vein within the liver through an 18-gauge needle that had been inserted into the fetal liver substance itself. Reversal in utero of mild hydrops with survival did occur in one case with their technique. They reported no fetal complications. Ultrasound-guided umbilical venipuncture was used to sample fetal blood in 13 cases and to transfuse one hydropic fetus in a report from Hobbins et al.,[2] but the details of the hydropic case and subsequent outcome were not given. They used a 25-gauge needle and emphasized transplacental placement with transplanar (scan plane across axis of needle) needle imaging with a linear array transducer.[2] Here, the technique of Hobbins et al. was modified by use of a needle with a larger, stiffer shaft that allowed for relatively easy transamniotic placement with coplanar (axis of needle parallel to scan plane) ultrasound guidance. The transcutane-

ous-transmural catheter sleeve allowed easy movement of the transfusion needle and no fluid leakage occurred.

Transamniotic ultrasound-guided fetal umbilical venipuncture offers direct access to the fetal circulation for sampling as well as infusion and may offer the severely hydropic fetus a greater probability of survival. This technique might subject the fetus to less organ trauma than the transhepatic approach advocated by Ch. de Crespigny et al.[3] It is premature to propose the replacement of the more traditional techniques of intraperitoneal transfusion in the care of the less severely affected fetus until more experience is acquired, but the intravascular approach may prove superior.

Factors influencing nonstress test results in multiple gestations

Peter Patkos, M.D., Marc Boucher, M.D., Paula M. Broussard, R.N., Jeffrey P. Phelan, M.D., and Lawrence D. Platt, M.D.

Los Angeles, California

The nonstress test remains the most widely used method of antepartum fetal health assessment in multiple gestations. However, few data are available on factors influencing its results in those cases. Our observation on 530 such tests has shown results similar to those in singleton gestations. Prematurity was associated with a higher rate of nonreactive tests; however, order and mode of presentation had no impact. (Am J Obstet Gynecol 1986;154:1107-8.)

Key words: Twins, multiple gestation, nonstress test, antepartum testing

Among methods of antepartum fetal health assessment in use today the nonstress test (NST) appears to be the most widely used. The reactivity of the fetal heart rate (FHR) has been shown to be a function of gestational age in singleton fetuses.[1] Other factors that may influence results are less well known or characterized. In multiple gestations, antepartum fetal health assessment also relies mainly on the NST. Therefore we designed this study to determine which factors in multiple gestations might influence test results.

Material and methods

Our study was both retrospective and prospective: the retrospective part between January 1, 1980, and June 30, 1983, and the prospective part between July 1, 1983, and March 12, 1984. During that period of time, at our institution, we delivered 61,932 infants, including 610 multiple gestations (0.98%). Ninety sets of multiple gestations (183 fetuses) had at least one NST performed. Fifty-one sets in the retrospective period (one triplet gestation) had 218 NSTs and 39 sets in the prospective (two triplet gestations) had 312 NSTs. Two fetuses died in the antepartum period before the onset of antepartum testing and were thus excluded from the study. Thus 530 individual NSTs in fetuses that were alive at the onset of testing were available for analysis. All NSTs were performed simultaneously on each fetus of a multiple set, the patient being in a semi-Fowler position. A reactive NST was defined as the occurrence of two FHR accelerations of 15 bpm and 15 seconds' duration in a 10-minute window. All other results were considered nonreactive. Statistical analysis of discrete data was performed with χ^2 test with Yates' correction when appropriate. Significance was set at a p value <0.05.

Results

Table I shows the distribution of NST results by gestational age. Globally, 86.6% (459 of 530) of the tests were reactive. Fetuses between 26 and 31 weeks' gestation had a reactive NST in only 68.1% of cases (49 of 72), while those between 32 and 36 weeks had a

37	43	91.5	4	8.5	47
38	32	100	0	0	32
39	23	92.0	2	8.0	25
40	11	91.7	1	8.3	12
41	9	90.0	1	10.0	10
42	2	100	0	0	2
Total	459	(86.6)	71	(13.4)	530

reactive NST in 87.9% of cases (290 of 330), $p < 0.001$, and those between 37 and 42 weeks in 93.8% of cases (120 of 128), $p < 0.001$. The difference between these last two groups was not significant.

Order of fetuses at the time of testing had no influence on results as reactive NSTs were observed in 85.8% of first babies (224 of 261) and 87.4% of second babies (235 of 269).

Finally fetuses in breech presentation were more likely to have a nonreactive NST (29 of 164, 17.7%) than those in vertex or transverse-oblique presentations (42 of 366, 11.5%). However, this difference was not statistically significant.

Comment

The NST remains the most widely used method of antepartum fetal assessment. Previous studies have demonstrated that the frequency of FHR accelerations is lower in premature fetuses. This high nonreactivity rate is considered to be related to the immaturity of the central nervous system and/or myocardium and to a higher baseline heart rate; the heart often cannot accelerate sufficiently to meet the accepted criteria of reactivity.[1] Our study in multiple gestations confirms this previous observation made in singleton gestations with a constant progression in the rate of reactivity between 26 weeks and term. The overall rate of reactivity in our multiple gestations is comparable to what has been observed in singleton pregnancies with 86.6% of tests being reactive.[2] Furthermore there was no difference in the rate of reactivity depending on the order of fetuses at the time of testing. However, we had no way of knowing if that order remained the same during all tests performed on each fetus. Thus we cannot conclude that this relation remained the same as that at delivery. Nonetheless it is noteworthy that the second fetus (at the time of testing) had a similar rate of reactivity, in comparison with that of the first fetus, as many studies have shown higher perinatal morbidity and mortality rates for the second twin. On careful review of these data, antepartum complications do not seem to be a significant factor with regard to this fact but rather it seems that intrapartum events must play a more important role.

Finally, fetal presentation had no significant influence on the rate of reactivity in multiple gestations. A recent report by White and Cibils[3] has shown a lower incidence of intrapartum FHR accelerations in breech presentations compared with that expected with a vertex presentation, but these data do not support this conclusion in the antepartum period.

Our data show that special care must be taken in the interpretation of a nonreactive NST in multiple gestations, especially at a shorter gestational age. The likelihood of a falsely nonreactive NST in those fetuses <32 weeks' gestation is significant, as 31.9% of fetuses had a nonreactive NST in that gestational age group. Logically, one does not want to compromise a healthy fetus by delivery in multiple gestations simply because one of them is nonreactive. This is particularly true in the premature age group. Therefore there is a definite need to carefully evaluate other means of assessing the fetus when one or more tests of fetal well-being suggest compromise.

Failure of nonstress test and Doppler-assessed umbilical arterial blood flow to detect imminent intrauterine death

R. L. A. Erskine, M.B., J. W. K. Ritchie, M.D., A. Zaltz, B.Sc., M.D., and T. Tice, R.N.
Toronto, Ontario, Canada

An unexplained intrauterine death occurred within 12 hours of a normal reactive nonstress test. Furthermore the umbilical arterial impedance measured by pulsed Doppler ultrasound was also normal.
(AM J OBSTET GYNECOL 1986;154:1109-10.)

Key words: Nonstress test, Doppler ultrasound, blood flow, umbilical artery, intrauterine death

The nonstress test is now widely regarded as being one of the best methods of assessing fetal well-being particularly in the management of the postterm fetus. Nevertheless intrauterine deaths have occurred after a normal tracing. Most of these were due to acute events but a small number remain unexplained.

Pulsed Doppler ultrasound permits both quantitative and qualitative calculation of blood flow velocity within fetal vessels, particularly the umbilical artery, and fetuses with a high impedance within this vessel have been found to be seriously compromised.[1]

A case is presented in which a fetus having both a normal reactive heart rate tracing and a normal umbilical arterial impedance died in utero from unexplained causes some 12 hours later.

Case presentation

A 38-year-old primigravid woman first presented at 13 weeks of amenorrhea and gestation was confirmed 3 weeks later by ultrasound.

The antenatal course was uneventful until no fetal heart movement was detected at term plus 11 days. A nonstress test the previous day was reactive (Fig. 1). On ultrasound scanning at the same time there was no oligohydramnios and the placental architecture was Grade I. The umbilical arterial impedance measured by pulsed Doppler ultrasound was also within the normal range (Fig. 2) previously established with the same technique.[1] Intrauterine death was confirmed on ultrasound the next morning. Delivery was effected within 24 hours and the fetus was female, was grossly normal apart from some skin maceration, and weighed 3360 gm, with no evidence of cord entanglement or torsion. There was no retroplacental clot.

Kleihauer-Betke test immediately after birth detected no fetomaternal bleeding. Glycosylated hemoglobin (hemoglobin A_{1c}) was 0.052 (normal range = 0.03 to 0.06). Results of a TORCH screen (toxoplasma, rubella virus, cytomegalovirus, and herpesvirus) were

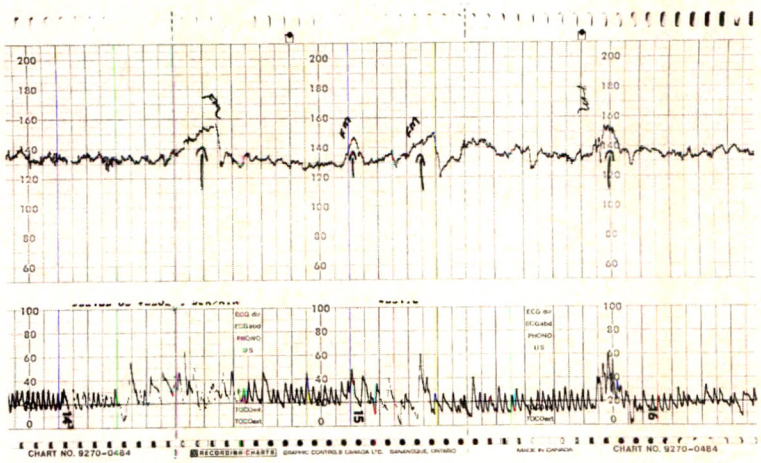

Fig. 1. Typical section of the normal fetal nonstress test recorded less than 12 hours before intrauterine death.

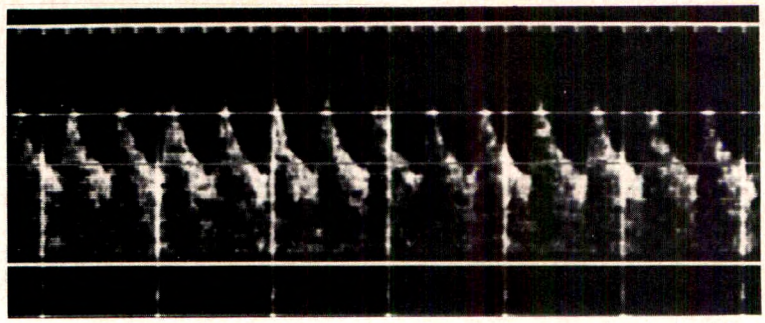

Fig. 2. Normal umbilical arterial sonograms obtained from the fetus less than 12 hours before intrauterine death. The pulsatility index (peak-to-peak height/mean height) was 0.57 (upper limit of normal = 0.85).

unchanged from those of a similar screen performed at 13 weeks' amenorrhea. There was no change in maternal hemoglobin concentration during the 24-hour period in which fetal death occurred. Maternal blood group was O positive but with a positive direct Coombs' test, indicating that the red blood cells were coated with complement, although this was subsequently shown to be due to cold agglutinins.

The placenta weighed 600 gm and histologic examination detected only one small area (1 by 1 by 1 cm) of infarction near the periphery. The cord, measuring 32 cm in length, contained three blood vessels with no evidence of thrombosis or inflammation.

Postmortem examination of the fetus revealed no gross anatomic or histologic abnormality except extensive skin and brain maceration.

Comment

Intrauterine death after a normal reactive nonstress test has been reported, but the vast majority of such deaths have been due to acute accidents of the cord, infection, fetal anomalies, or abruptio placentae. The unexplained death of a normal fetus within 48 hours of a normal reactive nonstress test has only been reported twice, once within 24 hours of a normal tracing and the other immediately following a normal reactive tracing. The case presented is the first such death to be documented within a short period of a normal umbilical arterial impedance measurement. We view this as a cautionary warning to those groups examining this technique as a research procedure and particularly to those advocating it as a reliable and sensitive measure of fetal well-being.[2]

We thank Dr. M. Barkin for permission to report his case.

The in vivo effect of amniotic fluid on endocervical microflora

Robert M. Patterson, M.D., Jorge D. Blanco, M.D., Ronald S. Gibbs, M.D., and P. J. St. Clair

San Antonio, Texas

To test the in vivo effect of amniotic fluid on endocervical microflora, we performed endocervical cultures before and after rupture of the membranes in 20 patients in term labor. There were no significant qualitative or quantitative differences in aerobic or anaerobic isolates for up to 4 hours after membrane rupture. Group B streptococci, isolated in two patients (10%), persisted after rupture of the membranes. These data suggest that endocervical cultures are minimally influenced by rupture of the chorioamnion for at least 4 hours. (Am J Obstet Gynecol 1986;154:1111-2.)

Key words: Amniotic fluid, bacterial inhibition

Endocervical cultures are commonly recommended in patients with spontaneous rupture of the membranes before labor.[1] Although amniotic fluid is known to have bacterial inhibitory activity in vitro,[2] the effect of amniotic fluid on endocervical cultures is not established. The purpose of this study was to evaluate the in vivo effect of amniotic fluid on the endocervical microflora.

At Medical Center Hospital in San Antonio, Texas, patients presenting in uncomplicated labor at term were evaluated as possible candidates for study. Inclusion criteria were an intact chorioamnion and no digital examination with bactericidal or bacteriostatic agents. Patients later found to have meconium-stained amniotic fluid were excluded.

Consenting patients underwent sterile speculum examination. The cervix was visualized and, with the use of prereduced swabs, endocervical samples were plated directly onto appropriate media for aerobes, anaerobes, and genital mycoplasmas. The chorioamnion was then ruptured according to standard obstetric indications, and before repeat digital examination, sterile speculum examination and culture were repeated.

Bacterial and mycoplasma isolates were identified by use of standard techniques. The plate streak methodology was used for bacterial semiquantitation.

To study the effect of increasing duration of ruptured membranes on culture results, the patients were grouped according to time interval of rupture of the membranes between cultures. Group 1 included patients with rupture of the membranes <2 hours between cultures, and group 2 comprised patients with rupture of the membranes ≥2 hours between cultures. Longer durations of ruptured membranes were not possible because of the need to examine patients in labor. With each patient used as her own control, we evaluated numbers of bacterial isolates before and after rupture of the membranes by paired Student's *t* test. A value of $p \leq 0.05$ was considered significant.

Table I. Bacterial isolates in 20 patients in labor at term before and after rupture of the membranes

Isolates	Patients with positive culture			
	Before rupture of membranes		After rupture of membranes	
	n	%	*n*	%
Lactobacillus sp.	18	90	19	95
Staphylococcus epidermidis	14	70	16	80
Ureaplasma urealyticum	12	60	13	65
Bacteroides bivius	8	40	8	40
Candida sp.	4	20	3	15
Mycoplasma hominis	3	15	2	10
Bacteroides fragilis	2	10	3	15
Anaerobic *Streptococcus* sp.	1	5	2	10
Group B streptococci	2	10	2	10
Enterococci	0	0	2	10
Clostridium sp.	2	10	2	10

Twenty patients were admitted into the study. Groups 1 and 2 contained 10 patients each. Mean age and parity were 24 years and 1.6, respectively. Mean gestational age was 41 weeks. Age, parity, and gestational age were similar between groups 1 and 2.

In group 1, cervical dilatation was 5.3 ± 1.5 cm at admission and 6.8 ± 2.1 cm at the time of repeat culture, whereas in group 2, cervical dilatation was 3.3 ± 0.63 cm initially and 5.6 ± 2.6 cm at the time of

repeat culture. There was no significant increase in cervical dilatation in either group.

Isolation rates of organisms are shown in Table I. Group B streptococci were isolated in two patients. There were no significant changes after ruptured membranes.

In groups 1 and 2, the duration of rupture of the membranes was 0.72 ± 0.36 and 3.72 ± 0.70 hours, respectively. In group 1, the mean number of aerobic bacterial isolates was 2.0 ± 0.47 before rupture of the membranes and 2.1 ± 0.57 after rupture of the membranes. There were 1.2 ± 1.0 anaerobic isolates before rupture of the membranes and 1.1 ± 1.3 anaerobic isolates after rupture of the membranes. The numbers of aerobic and anaerobic isolates did not change significantly after rupture of the membranes. In group 2 there were 1.8 ± 0.42 aerobes before and 2.2 ± 0.79 aerobes after rupture of the membranes. There were 0.8 ± 0.9 and 1.3 ± 0.95 anaerobic isolates before and after rupture of the membranes. In group 2 there were no significant differences in numbers of aerobic and anaerobic isolates after rupture of the membranes. Group B streptococci, present in two of 20 patients, persisted after rupture of the membranes. There were no effects of rupture of the membranes on isolation rates of genital mycoplasmas.

Semiquantitation of the 77 bacterial isolates revealed that 25 (33%) increased in number, 19 (25%) decreased in number, and 35 (43%) remained unchanged after rupture of the membranes. Aerobes and anaerobes behaved similarly with respect to semiquantitation.

Endocervical cultures are commonly performed in patients with preterm spontaneous rupture of the membranes.[1] Research protocols collect data on endocervical infection as a pathogenetic mechanism in premature labor or premature membrane rupture, and clinical protocols attempt to identify carriers of group B streptococci of *Neisseria gonorrhoeae*. Research and clinical decisions depend on the reliability of such cultures. The in vitro bacterial inhibitory activity of amniotic fluid is well described. Although cross-sectional studies have demonstrated more anaerobic isolates among patients with preterm ruptured membranes, possible in vivo effects of amniotic fluid on culture results were not considered. In the present longitudinal study, endocervical bacterial isolates did not change qualitatively or semiquantitatively after ruptured fetal membranes. It is important that group B streptococci, present in 10% of patients, persisted in the presence of amniotic fluid. These data suggest that endocervical cultures are minimally influenced for at least 4 hours after rupture of the chorioamnion.

Single-dose trimethoprim-sulfamethoxazole prophylaxis for cesarean section

Vijaya Ganesh, M.D., Joseph J. Apuzzio, M.D., Benjamin Dispenziere, M.D., Kiritkumar Patel, M.D., Blair Bergen, M.D., and Donald B. Louria, M.D.

Newark, New Jersey

Single-dose trimethoprim-sulfamethoxazole prophylaxis after clamping of the umbilical cord decreased the rate of endomyometritis in high-risk patients by 50% when compared with placebo. This drug combination may affect the normal flora of the cervix the least so that superinfections should be rare. (AM J OBSTET GYNECOL 1986;154:1113-4.)

Key words: Prophylaxis, cesarean section delivery, endomyometritis

We evaluated the efficacy of a single dose of trimethoprim-sulfamethoxazole prophylaxis for cesarean section in high-risk patients (less than age 21). We chose this group of patients since data from our previous studies have indicated that patients less than 21 years of age are at a higher risk for developing postoperative infections than other groups.

Material and methods

The study included 57 patients and was conducted from November, 1983, to December, 1984. All patients who were less than 21 years of age and undergoing cesarean delivery at the University Hospital of the New Jersey Medical School in Newark, New Jersey, were considered candidates for the study. Informed consent was obtained from all participants. Candidates were excluded from the study if there was evidence of any of the following: treatment with an antibiotic within 2 weeks of delivery, any active infection and/or elevated temperature at the time of delivery, penicillin allergy, sulfa allergy, or internal fetal monitoring with either a scalp electrode or a uterine pressure probe to eliminate a possible cause of infection.

Patients were randomly divided into two groups. Group 1 received placebo and consisted of 28 patients; group 2 (29 patients) were given 240 mg of trimethoprim and 1200 mg of sulfamethoxazole in one dose intravenously after clamping of the cord at the time of delivery.

The patients were observed postoperatively for signs and symptoms of infection. A diagnosis of endomyometritis was determined by a temperature elevation ≥100.4° F on any two occasions during any 24-hour period from the second postpartum day until discharge from the hospital. A complete physical examination was performed to localize the site of infection, and complete blood count with differential count and urine, endocervical, and blood specimens for culture were obtained. Diagnosis of post–cesarean section endomyometritis was made on the basis of an elevated temperature, uterine tenderness, and the absence of another focus of infection. The majority of cases of infection had foul-smelling lochia. However, this was not considered necessary to make the diagnosis. Urinary tract infection was defined as fever ≥100.4° F and a positive urine culture of 10^5 organisms per milliliter or more. Wound infection was defined as fever ≥100.4° F and an abnormal-appearing wound with cellulitis or a wound draining purulent material. The treatment of endomyometritis included clindamycin and gentamicin or ticarcillin and clavulanic acid in appropriate doses. Statistical analysis of the data was performed by computer with the use of Fisher's exact test.

Table I. Comparison of groups

	Placebo	*Trimethoprim-sulfamethoxazole prophylaxis*
Number	28	29
Age (yr) (mean)	17.3	16.9
Gravidity	1.4	1.7
Vaginal examinations	3.9	4.1
Duration of labor (hr)	9.6	8.0
Duration of rupture of membranes (hr)	4.5	2.1
Elective repeat cesarean section	12	11

Results

The study groups were similar with regard to their demographic and obstetric parameters (Table I). All

patients were of the lower socioeconomic class and more than 90% were black. There was no statistically significant difference between the two groups for any of the variables studied.

Of the studied population, 13 of 28 (46%) who received placebo developed endomyometritis after delivery compared with six of 29 (21%) who received single-dose prophylaxis with trimethoprim-sulfamethoxazole ($p = 0.036$ Fisher's exact test). The incidence of urinary tract infection and wound infection was similar.

The organisms most frequently isolated from patients who developed endomyometritis were peptococci, peptostreptococci, and *Escherichia coli.*

Comment

The results from this study are similar to those of previous studies that we have performed, indicating that prophylactic antibiotics for patients who were delivered by cesarean section decreased infection rates by approximately 50%.[1] Patients less than 21 years of age per se have been shown to have a higher rate of infection from our previous studies.

The high rate of endomyometritis in the placebo group may be related in part to our patients' lower socioeconomic status. Cunningham et al.[2] reported a similar incidence of endomyometritis in a similar population.

The results with trimethoprim-sulfamethoxazole administration are interesting since this combination would not be expected to reduce the anaerobic bacteria flora. Nevertheless, the combination did reduce infection by about 50%. These findings suggest several possibilities: that aerobes may be an important cause of post–cesarean section endomyometritis, that they are an active component of a mixed infection, or that the prophylactic regimen may have had some effect against the anaerobic flora. It is also possible that reduction in the aerobic flora permits postcellular defenses to cope more successfully with anaerobic invaders.

A single dose of the combination of trimethoprim-sulfamethoxazole deserves additional studies as a prophylactic agent. Also a single dose of antibiotic should save costs and be associated with fewer adverse reactions when compared with multiple dose regimens of antibiotic prophylaxis.

Hydrops fetalis and chromosomal trisomies

Bonnie G. Landrum, M.D., Dana E. Johnson, M.D., Ph.D., Bruce Ferrara, M.D., Stephen J. Boros, M.D., and Theodore R. Thompson, M.D.

Minneapolis and St. Paul, Minnesota

Three patients with trisomy 21 and one with trisomy 13 associated with nonimmunologic hydrops fetalis are presented. Analysis of previous nonimmunologic hydrops fetalis, which included chromosomal trisomies, and the present study yields an overall incidence of 7% for chromosomal trisomy disorders in live-born infants with nonimmunologic hydrops fetalis. Our data emphasize the need for chromosomal analysis of neonates with nonimmunologic hydrops fetalis. (Am J Obstet Gynecol 1986;154:1114-5.)

Key words: Hydrops fetalis, chromosome, trisomy

Hydrops fetalis can be divided into immunologic and nonimmunologic categories. As Rh disease has markedly diminished, nonimmunologic hydrops fetalis has become the most common type. Fourteen infants with nonimmunologic hydrops fetalis were managed at the University of Minnesota Hospitals from 1978 to 1983. Four patients (29%) had chromosomal trisomies (trisomy 21, n = 3; trisomy 13, n = 1).

From the Division of Neonatology, Department of Pediatrics, University of Minnesota Hospitals, Minneapolis, and Children's Hospital of St. Paul.
Received for publication December 16, 1985; accepted January 2, 1986.

Patients

Maternal-fetal and neonatal characteristics are outlined in Table I. Ultrasonography revealed prenatal

Table I. Clinical data

Patient No.	*Pregnancy complications*	*Birth weight (gm)*	*Gestational age (wk)*	*Phenotypic characteristics*	*Genotypic diagnosis*	*Outcome*
1	Polyhydramnios; fetal scalp, thoracic edema	3040	35	Facial and truncal edema; ascites; features of Down's syndrome after diuresis	47,XY + 21 (skin fibroblasts)	Alive
2	Normal ultrasound at 20, 27 wk; polyhydramnios; fetal edema, ascites just before delivery	3840	35	Truncal edema, ascites	47,XY + 21 (skin fibroblasts)	Death, day 2
3	Premature labor	2540	32	Anasarca; features of Down's syndrome after diuresis; endocardial cushion defect with cor triatriatum (autopsy)	47,XY + 21 (bone marrow chromosomes)	Death, day 20
4	Severe preeclampsia with congestive heart failure	2460	34	Anasarca; multiple anomalies consistent with trisomy 13	47,XX + 13 (skin fibroblasts with G banding)	Death, day 1

polyhydramnios and fetal edema in two cases, with hydrops appearing in one fetus just before delivery, after normal ultrasonographic examinations at 20 and 27 weeks. All four infants required extensive ventilatory support with oxygen at birth. All had significant edema and ascites at birth. Evaluation ruled out renal, gastrointestinal, hematologic, and viral etiologies of the nonimmunologic hydrops fetalis. Features of Down's syndrome became evident after diuresis in the two patients who survived more than 2 days. The third infant had Down's syndrome (death on day 2) diagnosed by skin fibroblast cultures. The fourth infant died soon after birth and had multiple anomalies consistent with trisomy 13.

Comment

Chromosomal trisomy disorders are considered rare causes of nonimmunologic hydrops fetalis. Only 25 cases (trisomy 21, n = 17; trisomy 18, n = 6; trisomy 13, n = 2) have been previously reported. Analysis of previously reported series of nonimmunologic hydrops fetalis that included infants with chromosomal trisomies and the present study yields an overall incidence of 7% in live-born infants with nonimmunologic hydrops fetalis, with a range from 3%[1] to 29% in the present study. However, the incidence of chromosomal trisomies could be higher or lower since hydropic fetuses may die in utero. Hydrops fetalis has been noted in first- and second-trimester fetuses with trisomy 21, 18, and 13.[1, 2] The cause of edema in chromosomal trisomies is unknown. Fetal hypoxia due to placental abnormalities may result in capillary endothelial damage, leading to increased capillary permeability and subsequent edema formation.

The association between nonimmunologic hydrops fetalis and chromosomal trisomies has valuable clinical applications. When fetal edema is diagnosed via ultrasonography, amniocentesis and fetal karyotype determination should be considered. Hydropic fetuses may have at least a 7% chance of a chromosomal trisomy, and female fetuses have the additional risk of having an XO karyotype (Turner's syndrome). Chromosomal abnormalities should always be considered in the differential diagnosis of nonimmunologic hydrops fetalis in the fetus and neonate. Their features are often distorted by edema, thus obscuring the phenotypic characteristics of the common trisomies.

Excretion of varicella–herpes zoster virus in breast milk

Irene B. Frederick, M.D., Roberta J. White, Ph.D., and Suzanne W. Braddock, M.D.
Omaha, Nebraska

Two cases involving breast-feeding and varicella–herpes zoster virus infection are presented. The possibility of viral excretion in the breast milk and its effects on continued breast-feeding are discussed. In neither case was the virus isolated from the breast milk. (AM J OBSTET GYNECOL 1986;154:1116-7.)

Key words: Lactation, varicella–herpes zoster virus, breast milk

Both chickenpox and herpes zoster infections occur during the reproductive years. It seems possible that a breast-feeding infant could acquire herpes zoster infection from an infected mother either by direct skin contact during nursing or by consuming virus-contaminated milk. An extensive search through clinical and basic science literature did not produce relevant data on the excretion of the varicella–herpes zoster virus in breast milk or on the clinical consequences of continued breast-feeding during a maternal infection. We recently saw one case of chickenpox and one case of herpes zoster dermatitis in lactating mothers. In both cases we monitored the method of feeding, the course of the disease in the mother, the possible presence of excreted virus in breast milk, and signs of herpes zoster infection in the infant.

Case reports

Case No. 1. A 33-year-old woman, gravida 5, para 3-0-2-3, 6 months post partum, lactating, and with a history of childhood chickenpox, presented with cutaneous vesicles involving the T4-5 dermatome on the left back and side. The breast was not involved. The lesions were painful grouped, classic herpetiform vesicles on an erythematous base, with patches varying in size from 2-4 cm. Vesicles progressed from clear to necrotic in the usual sequence during the next few weeks after the initial presentation. Within 24 hours of the appearance of the lesions, milk was expressed separately from each breast directly into culture tubes. Milk was cultured on diploid human fibroblasts and then examined for cytopathic effect. After the appropriate incubation period, the cultures proved negative for varicella–herpes zoster virus. The lesions were treated symptomatically and with topical acyclovir beginning at the time of presentation. On the sixth day after eruption crusting began, and by 2 weeks after eruption the lesions were healing. At the time of presentation the infant had been solely breast-fed with only recent introduction of solids. She had nursed on the affected side on the day lesions were first noted. Breast-feeding was allowed to continue, and position changes were used to avoid infant contact with lesions.

Case No. 2. A 21-year-old woman, gravida 2, para 1-0-0-1, presented at 40 weeks' gestation with chickenpox contracted from her older child. No prior history of chickenpox was noted. Her immediate course was complicated by severe pulmonary compromise due to varicella pneumonia. Emergency cesarean section was performed. A healthy infant was delivered and treated prophylactically with zoster immune globulin and parenteral acyclovir. The infant did not develop clinical evidence of chickenpox and was discharged after 10 days' observation. In spite of her complicated postpartum course, the mother expressed an interest in maintaining lactation potential by using a breast pump. Milk production was established and sustained for several weeks, during which time the breast milk was cultured by the same methods as in Case 1. Again no growth of virus was obtained. Because of the very serious nature of the pulmonary complications, the mother never actually put the infant to the breast, nor was the expressed breast milk given to the infant. At 3 weeks post partum she elected to stop pumping and was offered lactation suppression.

Comment

In the first case reported, it was possible to prevent direct lesion contact and to maintain breast-feeding. The milk in this case did not reveal virus and no infant infection occurred. In the second case, extensive cutaneous lesions prevented actual breast-feeding because of the danger of neonatal varicella infection from maternal contact.[1] These two cases suggest that breast-feeding can continue during maternal herpes zoster infection without risk of herpes zoster infection via virus-contaminated breast milk and that, while the mother with chickenpox at delivery must be isolated from her infant, it may still be possible to safely give

her milk to her infant. Furthermore as maternal antibodies are excreted, anti–herpes zoster antibodies may be excreted in the milk, which help to further protect the infant from herpes zoster infection.[2] Additional data are needed to substantiate the safety of continued breast-feeding during maternal herpes zoster infection and of feeding expressed maternal milk from infected mothers to their infants.

We thank Michael K. Matthews, Ph.D., M.D., for manuscript revisions.

Folate deficiency presenting as pancytopenia in pregnancy

Francis X. Solano, Jr., M.D., and R. Bruce Councell, M.D.
Pittsburgh, Pennsylvania

Folate deficiency is a well-known complication of pregnancy. We present a case of folate deficiency with profound pancytopenia. Although this is a well-known consequence of folate deficiency, we wish to reemphasize this dramatic complication of pregnancy. (Am J Obstet Gynecol 1986;154:1117-8.)

Key words: Folic acid, pancytopenia, pregnancy

Pancytopenia is a well-known consequence of folate and vitamin B_{12} deficiencies. Vitamin B_{12} deficiency is distinctly unusual in pregnancy although levels may fall during the course of pregnancy secondary to hemodilution and vitamin B_{12} binders present in the serum. The incidence of folate deficiency varies from 0.2% to 30% during pregnancy depending on geographic locations and socioeconomic status. The routine use of folate supplementation has decreased the incidence in the United States. However, folate deficiency is the most common cause of macrocytosis in pregnancy. Hemoglobinopathies, hemolytic anemias, thyroid disease, and liver disease also cause macrocytosis.

Case report

R. D., a 21-year-old, gravida 2, para 1, white woman, presented at 38 weeks' gestation to Magee-Womens Hospital with ruptured membranes of 36 hours' duration. A routine blood count revealed pancytopenia with hemoglobin, 5.3 gm/dl; hematocrit, 16%; red blood cell count, 1.55×10^6; platelets, 33,000/mm^3; and a white blood cell count of 1900/mm^3 with 58% polymorphonuclear cells, 33% lymphocytes, 1% eosinophils, 2% bands, 1% metamyelocytes, 2% myelocytes, and 2% atypical lymphocytes.

The patient had an unremarkable past medical history. Her antepartum course was notable for persistent nausea and vomiting throughout the pregnancy. Hemoglobin and hematocrit at 18 weeks' gestation were 12.5 gm/dl and 36.8%, respectively. At 30 weeks, she continued to vomit and also had symptoms suggestive of reflux esophagitis with heartburn and an acid taste on lying flat and bending over. A repeat blood count was not performed. She claimed compliance with multiple vitamins, folate, and ferrous sulfate, which was standard prenatal care in the medical care center. From an obstetric standpoint, growth was appropriate by fundal height determination. From 18 to 30 weeks, she gained 4 kg; however, she gained only 1 kg from 30 weeks to delivery. At presentation she complained of fatigue and a sore tongue. She denied the use of antibiotics, anticonvulsives, and toxin exposure, and there were no symtpoms of malabsorption.

Physical examination revealed a well-developed woman with a yellow pallor in no acute distress. Vital signs included: blood pressure, 120/80 mm Hg; pulse, 120 bpm and regular; temperature, 37.8° C; respirations, 16/min. Skin was without petechiae. Sclera were icteric. Tongue was beefy red. No palatal petechiae or ulcerations were present. The chest was clear. The heart was tachycardiac with a Grade II/VI systolic ejection murmur. Abdominal examination was without hepatosplenomegaly. Fundal height was 38 cm, and fetal heart tones were 160 bpm. Mild contractions were occurring every 2 to 5 minutes. Cervix was 2 cm dilated at the −2 station with vertex presentation. Rupture of the membranes was confirmed. She did not have lymphadenopathy or sternal tenderness. Peripheral blood smear revealed hypersegmentation of polymorphonuclear cells with a seven-lobed nucleus. There was

Received for publication June 18, 1985; revised December 13, 1985; accepted December 23, 1985.
Reprints will not be available.

some anisocytosis and poikilocytosis with rare red blood cell fragmentation. Red blood cells were not grossly macrocytic on smear and on automated counter mean corpuscular volume was 103 and platelets were of normal size.

The initial impression was probable folate deficiency and concomitant iron deficiency, given the mild macrocytosis. She received four units of packed red blood cells and went into active labor. She was delivered of a viable female infant weighing 7 pounds, 12 ounces via spontaneous vaginal assist. Estimated blood loss was 700 ml. She had moderately severe postpartum atony. The infant had a hematocrit of 55% with a mean corpuscular volume of 120; white blood cells and platelets were normal.

Bone marrow examination of the mother 3 days post partum revealed a hypercellular marrow with megaloblastic myeloid predominance and decreased iron stores. Red blood cell folate was 64 μg/ml (normal 210 to 980 μg/ml); vitamin B_{12} level, 150 μg/ml (low normal); bilirubin, 3.2 mg/dl; direct bilirubin, 0.4 mg/dl; lactate dehydrogenase, 2627 units.

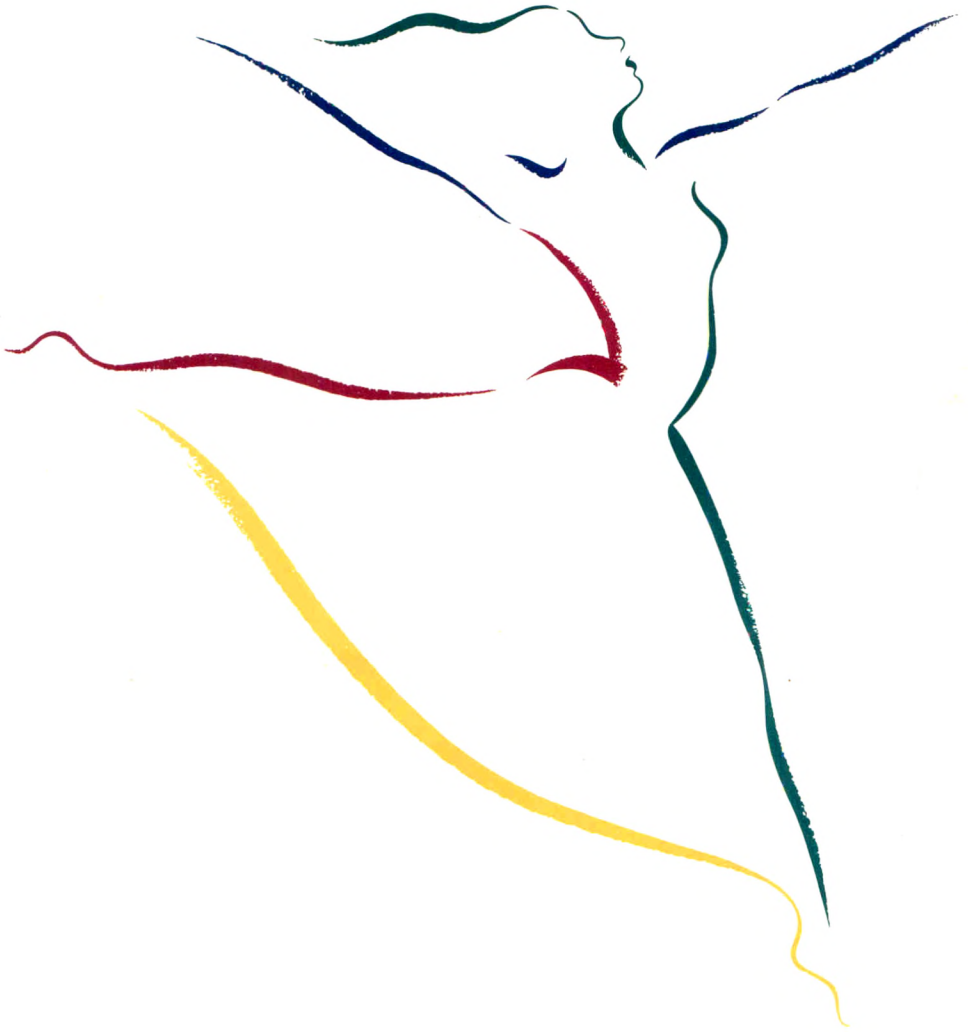
The patient received folate and ferrous sulfate. On discharge, white blood cell count was 15,900/mm^3; platelets, 117,000/mm^3; hemoglobin, 7.8 gm/dl; hematocrit, 23.8%; red blood cell count, 2.53 × 10^6; reticulocyte count went from 0.49% (6400/mm^3) to 5.4% (136,600/mm^3) during 5 days. Lactate dehydrogenase was 796 units. Six weeks post partum white blood cell count was 6000/mm^3; hemoglobin, 12.1 gm/dl; hematocrit, 36.6%; and platelet count, 324,000.

Comment

Folate requirements increase during pregnancy.[1, 2] Several authors estimate from 100 to 600 μg/day are needed to prevent folate deficiency in pregnancy. Placental and fetal needs coupled with the increased urinary excretion of folate are important in the genesis of deficiency. Gastrointestinal disturbances that occur during pregnancy can lead to dietary deficiency. A high-affinity binder of folate has been demonstrated in the serum of pregnant women as well.

We suspect that our patient did not exhibit profound macrocytosis from folate deficiency since she was also iron deficient. Generally one six-lobed polymorphonuclear white blood cell confirms the diagnosis of megaloblastic anemia. Both folate and vitamin B_{12} are required for deoxyribonucleic acid synthesis, and deficiency can lead to delayed synthesis that affects all cell lines and leads to resultant pancytopenia as in our patient.

Unfortunately, serum folate levels are not very useful in pregnancy because they tend to fall, yet the marrow is normoblastic. Red blood cell folate levels are somewhat more useful but may also be normal in the early phases of folate deficiency. Urinary formiminoglutamic acid excretion after histidine administration also has been useful in pregnancy. One must be cautious in the interpretation of vitamin B_{12} levels as in the present case. In addition to pregnancy, folate deficiency can also cause levels of vitamin B_{12} to be low because of overutilization of vitamin B_{12} in the absence of folate.



Folate deficiency has been linked to abruptio placentae, toxemia, neuropsychiatric syndrome, stillbirths, congenital anomalies, and decreased birth weights; however, subsequent studies have not supported these relationships. The role of folate in neural tube defects remains controversial.

Fortunately folate deficiency is on the decline in pregnant women with the use of prophylactic folate. Clinicians must still be watchful, particularly in patients with gastrointestinal disturbances of pregnancy, for the consequences of severe folate deficiency as occurred in our patient.

New imidazole for vulvovaginal candidiasis

Introducing

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

The Only 3-Day Cream*

*In non-pregnant patients, 3-day treatment is recommended. Treatment may be extended an additional 3 days, if necessary.

Please see brief summary of full prescribing information on last page.

SYNTEX

New imidazole for
vulvovaginal candidiasis

3-Day Cream

The shortest course of the preferred form

New Femstat®

vaginal cream 2.0%

(butoconazole nitrate)

The Only 3-Day Cream

- Symptom resolution comparable to 7-day miconazole cream with only 3 days of therapy.[2]
- Cream—the preferred form for prompt relief of vulvar itching and burning.[1]
- Low recurrence rate at one-month follow-up.
- Minimal incidence of side effects—limited to local irritation.
- Exclusive disposable applicators to enhance patient compliance.

1. According to a 12-month nationwide industry audit (ending October 1985), comprised of approximately 2,000 pharmacies. Vulvar burning occurred in 2.3% and itching in 0.9% of patients on Femstat.
2. Bradbeer CS, Mayhew SR, Barlow D: Butoconazole and miconazole in treating vaginal candidiasis. *Genitourinary Med* 61:270-272, 1985. (Study conducted in non-pregnant patients.)

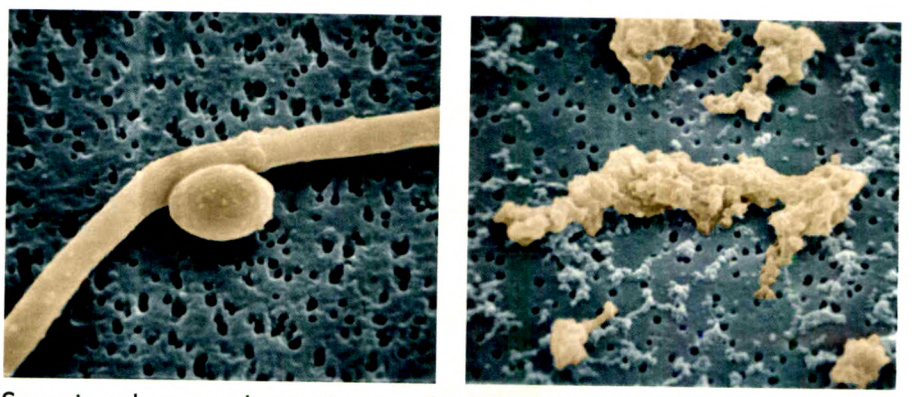
SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304



New imidazole for vulvovaginal candidiasis

New Femstat®

vaginal cream 2.0%

(butoconazole nitrate)

The Only 3-Day Cream

Scanning electron photomicrographs (5000X) of *Candida albicans* grown for 48 hours in serum (left), and in serum with 200 mcg/ml butoconazole nitrate (right).

Brief Summary

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General:
If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient:
Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis:
Animal studies have not been done.

Mutagenesis:
Mutagenicity studies were negative.

Impairment of Fertility:
Animal studies showed no impairment of fertility.

Pregnancy Category C:
Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers:
Use with caution.

Pediatric Use:
Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

OBSTETRICS & GYNECOLOGY

Fifth Edition

Edited by DAVID N. DANFORTH, Ph.D., M.D., F.A.C.O.G., F.A.C.S. and JAMES R. SCOTT, M.D., F.A.C.O.G. / With 86 Contributors

In OBG practice today, you need up-to-date, reliable information at your fingertips. Here it is—the new Fifth Edition of the recognized state-of-the-art text/reference for the practice of obstetrics and gynecology. It's patient-oriented and family-centered for the realities of today's medical care.

Written by experts

Authors are among the specialty's most prominent members—men and women who have special knowledge and talent both in the discipline as a whole and in its subspecialties.

Extensive revisions

The book has been extensively revised and updated, with new sections on medical and surgical complications of pregnancy. Basic science relationships are again emphasized.

New material

New or entirely rewritten chapters include

- *Ultrasound in OB/GYN*
- *Rh Isoimmunization*
- *Pregnancy-Induced Hypertension*
- *Intrauterine Growth Retardation*
- *Multiple Pregnancy*
- *Medical and Surgical Complications of Pregnancy*
- *Androgen Excess Sydromes*

Reviewer praise for the previous editions

". . . a panoramic approach to the entire subject . . . should be on every hospital's reference shelf."—*Postgraduate Medicine*

". . . The contributors summarize and offer their best ideas on the various aspects of our specialty. Each one sees that specialty from a different vantage point."—*JAMA*

". . . *Obstetrics and Gynecology* does indeed engender enthusiasm . . . an impressive array of authors . . . concise and well written . . . drawings, photographs, and photomicrographs are clear and well labeled . . . a valuable and comprehensive reference book for the office library."—*New England Journal of Medicine*

About 1,328 Pages. 1,097 Illustrations. 5th Edition, 1986. $75.00

More fine books from Lippincott provide essential information in your specialty

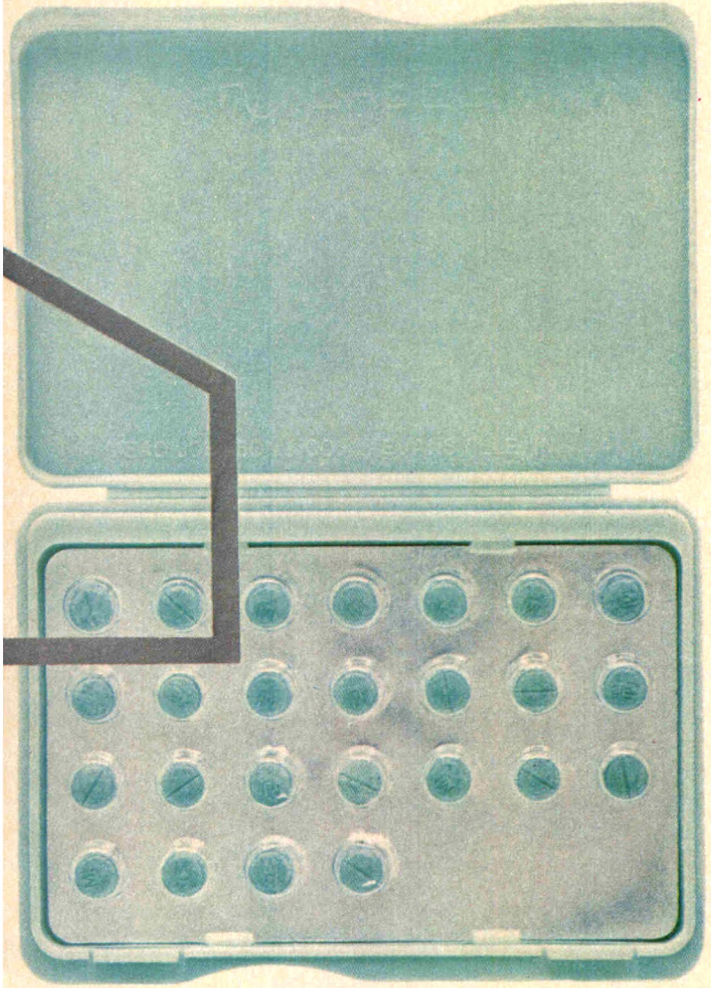
THE RIGHT CHEMISTRY



THE RIGHT REPLACEMENT FOR 17β-ESTRADIOL—17β-ESTRADIOL

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 USA MJL 5-4169

THE RIGHT REGIMEN

THE FIRST 25 DAYS OF THE MONTH— EVERY MONTH

ESTRACE is 17β-estradiol—just like the estrogen she made before menopause. Like the natural hormone, it follows a simple, well-known metabolic pathway, and it provides unsurpassed relief of postmenopausal vasomotor symptoms.

Micronized for good oral absorption, ESTRACE produces prompt, predictable serum levels of estradiol and estrone. Between cycles, ESTRACE is rapidly eliminated, providing estrogen replacement therapy that closely follows the premenopausal pattern . . . *for true cyclic therapy.*

Now it's in the ESTRACE Cycle Pak—an easy-to-carry compact, designed to deliver a starting dose of 2 mg in the preferred 25-day regimen. Cycle Paks delivering 1 mg daily are also available, if needed.

Mead Johnson LABORATORIES

For Brief Summary, please see following page.

ONLY NEW ESTRACE® (ESTRADIOL) TABLETS 1 mg and 2 mg CYCLE PAK HAS BOTH

ESTRACE® (estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

Warning

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If ESTRACE® (estradiol) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma—palliative therapy of advanced disease. *Vaginal Cream:* Atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Known or suspected cancer of the breast, except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: Estrogens increase the risk of carcinoma of the endometrium (See Boxed Warning). Prescribe cautiously in women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms. A 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease has been reported in women receiving postmenopausal estrogens. There is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders or (except in treatment of malignancy) with a history of such disorders in association with estrogen use; they should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis; when estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptives should be considered a clear risk. Hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Increased blood pressure occurs with use of estrogens in the menopause, and blood pressure should be monitored, especially with high doses. Diabetic patients should be carefully observed for decreased glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases; if this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General*—A complete medical and family history should be taken prior to initiation of therapy. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination. Conditions influenced by fluid retention, such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc, may develop. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. Pathologists should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops, discontinue use while cause is investigated. Administer with caution in patients with impaired liver function, metabolic bone diseases associated with hypercalcemia, or renal insufficiency and in young patients with incomplete bone growth. The following endocrine and liver function tests may be affected by larger estrogen doses: increased sulfobromophthalein retention; increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration. *Information for the Patient*—See text of Patient Package Insert. *Pregnancy Category X*—See Contraindications and Boxed Warning. *Nursing Mothers*—Administer to nursing mothers only when clearly necessary.

The 2-mg tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, frequently those who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported: *Genitourinary system*—Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*—Tenderness, enlargement, secretion. *Gastrointestinal*—Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice. *Skin*—Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism. *Eyes*—Steepening of corneal curvature; intolerance to contact lenses. *CNS*—Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*—Increase or decrease in weight, reduced carbohydrate tolerance, aggravation of porphyria, edema, changes in libido.

How Supplied: Tablets, containing 1 mg (lavender) and 2 mg (turquoise) micronized estradiol, in bottles of 100 and compacts of 25; Vaginal Cream, each gram containing 0.1 mg 17β-estradiol in a nonliquefying base containing purified water, propylene glycol, stearyl alcohol, white ceresin wax, glyceryl monostearate, hydroxypropyl methylcellulose, sodium lauryl sulfate, methylparaben, disodium edetate, and *t*-butylhydroquinone, in 1½-oz (42.5-g) tubes with calibrated plastic applicator for delivery of 1,2,3, or 4 g and in 1½-oz (42.5-g) refill tubes.

For Prescribing Information, please see physician package insert.

Gaucher's disease in pregnancy associated with portal hypertension

Moshe Mazor, M.D., Arnon Wiznitzer, M.D., Abraham Pinku, M.D., Miriam Katz, M.D., and Joseph R. Leiberman, M.D.

Beer-Sheva, Israel

A case is reported of Gaucher's disease in pregnancy associated with portal hypertension. Despite this rare and hazardous complication, the pregnancy, labor, and puerperium were uneventful. (AM J OBSTET GYNECOL 1986;154:1119-20.)

Key words: Gaucher's disease, pregnancy, portal hypertension

Gaucher's disease is the most common inherited metabolic disorder of glycolipid metabolism. The disease is an inborn error of intracellular metabolism characterized by abnormal storage of cerebroside in the reticuloendothelial system. On reviewing the literature, we were unable to find any case in which ascites was associated with Gaucher's disease in pregnancy. We report here the first case of confirmed Gaucher's disease in pregnancy associated with portal hypertension. Despite this serious complication, the prenatal course was uneventful, with good fetal outcome.

Case report

Z. M., a 23-year-old Jewish woman (gravida 1, para 0), was admitted at 12 weeks' gestation to the antenatal high-risk unit for evaluation. Her past medical history revealed that at the age of 4 she was diagnosed as having Gaucher's disease. At the age of 5 years she underwent a splenectomy, and at the age of 12 she had a fracture of the right femur head. A review of all the other organ systems was normal. A complete study of the patient's family revealed no other members that suffer from the disease.

On admission, physical examination revealed a blood pressure of 110/70 mm Hg, pulse of 90 bpm, respirations of 12/min, and temperature of 36.4° C. The patient was well nourished and asthenic, with a greatly enlarged abdomen. The skin had a buckwheat pallor. There was no icterus or cyanosis. Examination of the head and neck revealed no significant abnormality. The heart and lungs were normal and there was no adenopathy. The abdomen was markedly protuberant and the umbilicus everted. Some superficial venous distention was noted. A fluid wave was easily elicited. The liver edge was palpable 10 cm below the right costal margin; it was firm and not tender. The legs showed brownish pigmentation characteristic of Gaucher's disease. Uterine size was consistent with 12 weeks' gestation. The cervix was posterior, firm, and closed.

Ultrasound examination indicated a single fetus with crown-rump length of 54.7 mm. The abdominal scan revealed a huge ascites with no other abnormality.

Laboratory findings were as follows: The hemogram revealed anemia with a hemoglobin of 8.8 gm/dl; hematocrit of 27%; white blood cell count of 10,000/mm^3 with normal differential count; prothrombin time of 11 to 13 seconds; partial thromboplastin time of 30 to 34 seconds; platelets of 190,000/mm^3; and fibrinogen level of 590 mg/100 ml. The fasting blood sugar level, liver enzymes, and levels of creatinine, uric acid, and electrolytes were within normal limits.

The patient received supplements of iron and folic acid; she remained ambulatory and was followed up until onset of spontaneous labor. Consecutive measurements of uterine size and repeated ultrasound scanning indicated normal fetal growth. Because of the greater risk and the serious nature of the complications, frequent clinic visits were made with special attention given to liver function. Except for anemia, no other hematologic or gastrointestinal complications were observed during pregnancy.

At 41 weeks of gestation, labor began spontaneously and after 10 hours, a live, healthy female infant, weighing 3440 gm, was delivered. During labor the mother was carefully monitored for hematologic complications with cross-matched blood available on standby. The third stage of labor was uneventful, with a normal postpartum course. Three days after delivery, both she and her baby were discharged in a satisfactory condition. X-ray examination of the upper gastrointestinal tract revealed enlarged esophageal varices.

Comment

Gaucher's disease in pregnancy is rare. Most authors have concluded that in cases of Gaucher's disease in

From the Division of Obstetrics and Gynecology, Soroka University Hospital and Faculty of Health Sciences, Ben-Gurion University of the Negev.

Received for publication December 20, 1985; accepted December 27, 1985.

Reprint requests: Dr. M. Mazor, Division of Obstetrics and Gynecology, Soroka Medical Center, P. O. Box 151, Beer-Sheva 84101, Israel.

pregnancy, if close monitoring is undertaken, one can expect a good fetal outcome with no adverse effect on the mother. The majority of affected patients have a chronic low-grade anemia, which can usually be controlled with hematinics and rarely may require blood transfusion. Recently, Goldblatt and Beighton[1] reviewed the medical aspects of 21 pregnancies accompanied by Gaucher's disease and concluded that there are a few contraindications to pregnancy and no increased incidence of infertility, abortions, stillbirths, or congenital anomalies.

Although hepatosplenomegaly is commonly found in patients with Gaucher's disease, clinical complications of liver disease have rarely been reported. In nonpregnant patients, bleeding from esophageal varices as well as portal hypertension and ascites has been noted. These findings may be attributed solely to the massive presence of Gaucher's cells in the liver. Obliteration of the central veins and sinusoids and compression of the portal triads by Gaucher's cells and connective tissue seem to be the cause of the portal hypertension.[2]

Although in patients with portal hypertension there is an increased probability of bleeding varices as pregnancy nears term, no such complication was seen here. It is now clear that there is no evidence to indicate that Gaucher's disease significantly affects the course and prognosis of pregnancy in any adverse way. The case reported here confirms this evidence. Despite Gaucher's disease complicated by portal hypertension, the pregnancy, labor, and puerperium were uneventful.

Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography

Joshua A. Copel, M.D., Gianluigi Pilu, M.D., and Charles S. Kleinman, M.D.
New Haven, Connecticut

Fetal echocardiography is a well-established technique for the prenatal identification of congenital heart disease. One of the indications for its use is the presence of extracardiac anomalies, as such coexistent defects may have important implications for obstetric and neonatal management. We have reviewed the obstetric and pediatric literature to examine reported associations. If a fetus is suspected to have hydrocephalus, microcephaly, holoprosencephaly, agenesis of the corpus callosum, Meckel-Gruber syndrome, esophageal atresia, duodenal atresia, diaphragmatic hernia, omphalocele, or renal dysplasia, cardiac evaluation should be pursued. Furthermore, echocardiography may be of help in differential diagnosis of some anomalies (for instance, skeletal dysplasias). Maternal diabetes and phenylketonuria, as well as exposure to phenytoin, trimethadione, or isotretinoin, may result in multiple systemic defects, including congenital heart disease. (AM J OBSTET GYNECOL 1986;154:1121-32.)

Key words: Fetal echocardiography, extracardiac anomalies, congenital heart disease, prenatal diagnosis

High-resolution two-dimensional ultrasound has provided physicians with a tool for the prenatal diagnosis of malformations arising in virtually all parts of the body. A wide variety of diagnoses have been established from the gastrointestinal tract and the genitourinary, musculoskeletal, and central nervous systems.[1, 2] The information obtained can be directly applied for parental counseling and planning appropriate perinatal management.[3]

These techniques have been extended to the study of the heart as well.[4-7] At present, fetal echocardiography is directed toward pregnancies considered at particularly high risk of congenital heart disease[8]; the most frequent indication in our laboratory is a previous infant with congenital heart disease.[9] In these cases the risk of congenital heart disease is between 2% and 5%.[10] Fetal echocardiography has also been recommended for the evaluation of any fetus with extracardiac malformations.[8, 11]

Some extracardiac malformations carry a high risk of associated congenital heart disease, while for others the risk is low. We decided to examine those associations reported in the past in both the obstetric and pediatric literature, to help clarify this indication for the use of fetal echocardiography. The following categories will be considered: systemic anomalies, genetic syndromes, twins, and syndromes arising from selected environmental agents and from maternal metabolic diseases.

Most of our knowledge about the association of congenital heart disease with extracardiac malformations comes from studies of children identified because of cardiac abnormalities. Fewer studies have considered the reverse, that is, the incidence of congenital heart disease when extracardiac malformations have been identified. We shall review this issue from both sides. Significant differences may be anticipated in the findings of various studies depending on the method of case ascertainment. If the anomalies present are severe enough to cause a high perinatal mortality rate, these cases will probably be removed from consideration in pediatric studies. Conversely, an autopsy-based study may disclose clinically inapparent defects.

Systemic extracardiac malformations

The overall incidence of extracardiac malformations in children identified as having congenital heart disease

From the Fetal Cardiovascular Center, Section of Perinatology, Department of Obstetrics and Gynecology, and the Departments of Pediatrics (Cardiology) and Diagnostic Imaging, Yale University School of Medicine.

*Original report contained overlap between subgroups.

varies from 25% to 45% (Table I).[12-14] This variation appears to depend on the means of identification, with a lower incidence in clinical studies than in autopsy studies. The incidence also appears to be related to the type of cardiac defect identified.

Greenwood et al.[12] found that in abnormalities such as atrioventricular septal defects extracardiac malformations were present in more than 50% of cases, while atrial septal defects, ventricular septal defects, tetralogy of Fallot, and cardiac malpositions were associated with extracardiac malformations in about 30% of cases. They found a similarly high association with patent ductus arteriosus, although the frequency with which this occurs among otherwise normal premature infants makes it difficult to interpret the significance of this observation. While the other defects listed are all potentially diagnosable antenatally, the ductus is normally open in utero, and we shall not consider this further.

The second group Greenwood et al. identified included coarctation of the aorta, single ventricle, isolated pulmonary stenosis, and double-outlet right ventricle. Each of these was associated with extracardiac malformations in about 20% of cases. Additionally, the combination of pulmonary atresia with a ventricular septal defect was associated with extracardiac malformations in 18% of cases. All of the other structural congenital heart disease identified was associated with extracardiac malformations in <15% of cases.

Greenwood et al. additionally considered possible patterns of association between specific defects. They identified some trends, which we shall consider as we examine each system.

Central nervous system. The association of central nervous system lesions with congenital heart disease is relatively infrequent (Table I). Wallgren et al.,[13] in a study of 1000 children with congenital heart disease in a combination of clinical and autopsy findings, reported that 6% had associated central nervous system malformations. Of the 60 affected infants, 22 had unspecified brain anomalies, 17 had hydrocephalus, 12 had a meningomyelocele, and 17 had abnormalities of the sensory organs (eyes or ears). No specific pattern of relationships was found between the types of congenital heart disease and central nervous system abnormalities.

Greenwood et al.[12] found central nervous system abnormalities in 6.9% of 1566 infants with congenital heart disease, while Gallo et al.[14] reported an association in 3.2% of 1354 cases. Neither provided details concerning the types of central nervous system lesions present. Greenwood et al. failed to identify any specific pattern of congenital heart disease, but Gallo et al.[14] found an excess of ventricular septal defects (39%) among their population of 44 patients with congenital heart disease and central nervous system abnormalities.

Few clinical studies are available concerning the incidence of congenital heart disease in infants with congenital abnormalities of the central nervous system (Table II). In a series of 205 cases of isolated congenital hydrocephalus, nine cardiac malformations were found (4.5%).[15] Congenital heart disease, mainly ventricular septal defects, has occasionally been reported in association with Dandy-Walker syndrome[16, 17] and holoprosencephaly.[18] The latter association may be related to the frequent presence of concurrent trisomy 13.[19]

Congenital heart disease was observed in 15% of 47 patients found to have agenesis of the corpus callosum, with no specific pattern detected.[20] No specific association has been described between congenital heart disease and failure of neural tube closure (anencephaly, spina bifida), porencephalia, or hydranencephaly. As the causes of microcephaly are heterogeneous, including chromosomal aberrations, viral infections, and environmental agents (for instance, phenytoin, alcohol), congenital heart disease may often be seen.

A complex syndrome involving the presence of microcephaly, often with an occipital encephalocele, polycystic kidneys (Potter type III), polydactyly, cleft palate, and ambiguous genitalia is referred to as the Meckel syndrome (or Meckel-Gruber syndrome). The exact incidence of congenital heart disease is uncertain; however, Opitz and Howe[21] found a 14% incidence in a review of the previous literature. It is inherited in autosomal recessive fashion.

In a series of 27 cases of prenatally diagnosed hy-

drocephalus, Chervenak et al.[22] found congenital heart disease in four: two ventricular septal defects and one case each of tricuspid hypoplasia and tetralogy of Fallot. In our experience of 31 cases of isolated hydrocephalus, three cardiac abnormalities were seen: one pulmonary atresia with an intact ventricular septum and two atrioventricular septal defects.[23]

In summary, about 5% of cases of hydrocephalus diagnosed postnatally have associated congenital heart disease, and 10% to 15% of cases of hydrocephalus diagnosed prenatally have congenital heart disease. Central nervous system abnormalities are seen overall in 3% to 7% of infants identified as having congenital heart disease. Series of prenatally diagnosed congenital heart disease are too small to permit conclusions to be drawn and are biased by the fact that the central nervous system abnormality itself may be the indication for the fetal echocardiogram.

Mediastinal and respiratory defects. Structural defects of the trachea and esophagus are often concomitant, because of their close embryologic association; we shall consider them together with respiratory system anomalies. The association of these lesions with cardiac and noncardiac malformations is well-known and has been considered the consequence of a common insult, possibly environmental. Many acronyms have been applied to these syndromes (VATER: vertebral, anal, tracheoesophageal, radial, and/or renal; VACTEL: vertebral, anal, cardiac, tracheoesophageal, limbs; and VACTERL: a combination of the previous two).

Series of patients with tracheoesophageal fistula and/or esophageal atresia have shown congenital heart disease to be present in 15% to 40% of cases (Table II). An excess of atrial and/or ventricular septal defects has been reported in two series[24, 25] but has not been consistently noted, as shown in Table III.[26, 27] In one series, the presence of other extracardiac malformations was shown to have a strong influence on the likelihood of congenital heart disease; there was only an 8.3% incidence in isolated tracheoesophageal fistula or esophageal atresia, but the incidence rose to 22% if another extracardiac malformation was present.[27] The presence of congenital heart disease had a significant influence on mortality as well.

Wallgren et al.[13] reported 47 cases of esophageal atresia in 1000 infants with congenital heart disease; the incidence of tracheoesophageal fistula was not presented. Gallo et al.[14] found 14 cases of esophageal atresia in 1354 cases of congenital heart disease (1.0%) but also did not report the frequency of tracheoesophageal fistula. Among 1566 infants with congenital heart disease, Greenwood and Rosenthal[27] found tracheoesophageal fistula or esophageal atresia in only eight cases (0.5%), five of which were associated with other anomalies as well.

The most common type of cardiac defect found with esophageal atresia consisted of ventricular septal de-

fects, present in 12 of 47 (25.5%) of the series of Wallgren et al.[13] and 12 of 48 (25.0%) of that of Mellins and Blumenthal.[26] This is similar to the expected incidence of ventricular septal defect in an unselected population of children with congenital heart disease and may not represent a specific association.

Anomalies of the respiratory system were present in 5% of the cases reported by Wallgren et al.,[13] with hypoplastic lungs responsible for 19 of 52 (36.5%). Other lung abnormalities, primarily lobar, were the cause of an additional 25 cases, with 10 more caused by malformations of the trachea and larynx and choanal atresia. Greenwood et al.[12] found unspecified respiratory system anomalies in 58 of 1566 (3.8%) cases of congenital heart disease. The incidence of respiratory tract anomalies found by Gallo et al.[14] was similar, with anomalies present in 109 of 1354 (8.0%) cases of congenital heart disease.

Gastrointestinal system. The major forms of gastrointestinal abnormality diagnosed in the prenatal period are the bowel atresias. Of these the proximal obstructions tend to present earliest, as they are more likely to cause detectable increases in amniotic fluid volume or dilation of the stomach. Duodenal atresia is associated with trisomy 21 in 30% of cases. Touloukian[28] further reported that four of five infants with both trisomy 21 and duodenal atresia had malformations of the atrioventricular septum. Fonkalsrud et al.[29] noted that 17% of infants with duodenal obstruction had coexisting congenital heart disease. On the other hand, congenital heart disease is only found in 5.2% of infants with jejunal or ileal atresia (Table II).[30] This difference may result from the varying causes of the lesions. The duodenum is a solid core of tissue that undergoes vacuolization and recanalization between the fourth week and the sixth week of development. Failure of recanalization is often seen in association with abnormalities of pancreatic and terminal biliary development. Jejunoileal and colonic atresias are most often the result of ischemic injury occurring after the tenth week, when the gut has returned to the coelomic cavity.[28]

There have been wide variations reported in the frequency of association between imperforate anus and congenital heart disease (Table II). Greenwood et al.[31] reported a 12% incidence of congenital heart disease, most commonly tetralogy of Fallot and ventricular septal defects. Teixeira et al.,[32] in contrast, found that of 68 patients with anorectal anomalies, 15 (22%) had congenital heart disease, although 13 of these had other systemic and/or chromosomal anomalies. Three of their patients, all with multiple anomalies, had isolated patent ductus arteriosus, while an additional three patients had Ivemark syndrome (asplenia with congenital heart disease, see below). These figures may overestimate the true incidence, as congenital heart disease has also been reported in only 5.6% of patients with anorectal malformations.[33]

The overall incidence of intestinal malformations and obstructions in infants with congenital heart disease is 2% to 7% (Table I).[12-14] Wallgren et al.[13] found 22 cases of imperforate anus among their 1000 patients with congenital heart disease. Greenwood et al.[12] found that 12 of 1566 patients with congenital heart disease had imperforate anus (0.8%).

The heterotaxia syndromes (Ivemark syndrome, cardiosplenic syndrome) include the combination of congenital abnormalities of the spleen (asplenia or polysplenia), variable degrees of visceral heterotaxia, and complex congenital heart disease. Asplenia is usually associated with right atrial isomerism, and severe congenital heart disease is found in virtually all patients, frequently consisting of atrioventricular septal defects, often in association with transposition of the great arteries and anomalous pulmonary and systemic venous return. In this syndrome, the viscera take on a "bilateral right-sidedness" with bilateral trilobed lungs, and a midline liver with malrotation of the gut.[34]

Polysplenia syndrome is more often associated with "bilateral left-sidedness." There is left atrial isomerism, often with anomalous systemic (interrupted inferior vena cava with azygous continuation) and pulmonary venous return and atrioventricular septal defects.[34]

Identification of this syndrome is based on careful

evaluation of the visceral site as well as the segmental cardiac anatomy.[35] Prenatal diagnosis of heterotaxia syndrome has recently been reported,[36] and we have seen several examples in our laboratory as well.

It is important to differentiate this syndrome from Kartagener syndrome (immotile cilia syndrome; bronchiectasis, dextrocardia, and sinusitis), which is inherited in autosomal recessive fashion and appears to be associated with cardiac anomalies only if situs ambiguus is present.[33] Kartagener and Stucki[37] reviewed 116 cases of the syndrome and found only two with congenital heart disease, both having situs ambiguus. Holmes et al.[38] found congenital heart disease in two of 13 cases, but at least one of these had associated absence of the spleen.

Ventral wall defects. Defects of the anterior abdominal wall are traditionally divided into two groups based on the pathophysiologic features and resultant location of the defect. Gastroschisis is a full-thickness defect of the abdominal wall, usually occurring to the right of the umbilicus. It has been suggested to arise as a result of a localized failure of mesenchymal development with consequent ectodermal necrosis and evisceration. Complete nonrotation of the gut is invariably present.[39] It does not appear to be associated with an increased risk of congenital heart disease (Table II).

In contrast, omphalocele is one of a number of malformations of the abdominal wall that occurs because of failure of the normal infolding process of the borders of the embryonic disc. If this occurs low on the abdominal wall, involving the caudal fold, exstrophy of the bladder will result. If it is high, involving the cephalic fold, thoracic ectopia cordis is present along with sternal and diaphragmatic defects. If only the lateral folds are affected, then the intestines fail to return to the peritoneal cavity, and an umbilical defect covered by an amnioperitoneal membrane will result.

Omphalocele is associated with congenital heart disease in 19% to 32% of cases (Table II).[40, 41] The incidence of congenital heart disease seems to relate to which of the embryonic folds are involved. If only the caudal fold is involved, the heart is rarely affected. Greenwood et al.[40] found that 10% of neonates with lateral fold defects had congenital heart disease, with the frequency rising to 100% if the cephalic fold was affected. The most frequent defect was tetralogy of Fallot, which was present in 32% of patients with congenital heart disease.

The frequent association of upper midline defects with congenital heart disease has been given the eponym pentalogy of Cantrell. The full syndrome includes the presence of (1) a midline supraumbilical abdominal defect, (2) a defect of the lower sternum, (3) deficiency of the diaphragmatic pericardium, (4) deficiency of the anterior diaphragm, and (5) a congenital intracardiac abnormality.[42] In a literature review, Toyama[43] found a total of 36 cases of Cantrell syndrome, of which 18 (50%) had atrioventricular septal defects, six (18%) had ventricular septal defects, and four (11%) had tetralogy of Fallot.

The association of omphalocele with visceromegaly, macroglossia, and severe neonatal hypoglycemia has been termed Beckwith-Wiedemann syndrome. It has been reported to be associated with congenital cardiovascular malformations in 12 of 13 cases (92%). Seven of these 12 (58%) had structural congenital heart disease, while the other five had isolated cardiomegaly. No specific pattern of congenital heart disease could be determined.[44]

Diaphragmatic defects. Most congenital diaphragmatic defects occur through the foramina of Bochdalek or Morgagni. They may mimic congenital heart disease in and of themselves because of secondary cardiac malposition or vascular compression. There is also reported to be a significant association with true structural heart disease (Table II). Greenwood et al.[45] found that 11 of 48 patients with diaphragmatic hernia had associated congenital heart disease (22.9%). In a review of the literature before that report, they found a 9.6% (33 of 345) incidence. Greenwood's series included two patients with anterior herniation in association with omphalocele, one with tetralogy of Fallot, the other with ectopia cordis and intrinsic structural heart disease (possible Cantrell pentalogy), and two other patients with Down syndrome, which may account for the higher incidence in that series. Greenwood also noted, in a review of 1566 infants with congenital heart disease, that five (0.3%) had associated diaphragmatic hernia.

Genitourinary system. Consideration of associations between congenital heart disease and genitourinary malformations is complicated by the broad spectrum of disease entities encompassed by this group. Certain anomalies, such as unilateral obstruction of the ureter either at the renal pelvis or at the pelvic brim, are relatively benign. Others, such as bilateral renal agenesis, are catastrophic in and of themselves, while others, such as horseshoe kidneys and various genital malformations, are often associated with a wide variety of additional systemic abnormalities and chromosomal aberrations.

In their review of 1566 children with congenital heart disease, Greenwood et al.[12] found that 83 (5.3%) had associated genitourinary anomalies. Gallo et al.[14] noted that urinary anomalies were present in 110 of 1354 (8.1%) children with congenital heart disease and that 57 (4.2%) genital anomalies were present. No mention was made of whether any overlap existed between these two groups. Wallgren et al.[13] found genitourinary anomalies in 131 of 1000 patients with congenital heart disease (13.1%). Of these 131 patients, there were 30 (23%) with hydronephrosis, 24 (18%) with renal agenesis, 15 (11%) with horseshoe kidney, 28 (21%) with genital malformations, and 56 (43%) with other anom-

Table IV. Incidence of congenital heart disease in propositi with skeletal anomalies

Syndrome	*Inheritance pattern*	*Frequency of congenital heart disease (%)*
Short rib–polydactyly (3 types)[49, 50]	Autosomal recessive	Common*
Chondrodysplasia punctata[10, 51]	Autosomal recessive	Uncommon
Thrombocytopenia–absent radii[52]	Autosomal recessive	33
Fanconi[53]	Autosomal recessive	14
Crouzon[10, 33]	Autosomal dominant	Uncommon
Apert[54]	Autosomal dominant	10
Carpenter[55]	Autosomal recessive	3.2
Robin[33, 56]	Mixed	9
Arthrogryposis[57]	Mixed	Common†
Holt-Oram[58]	Autosomal dominant	Common‡
Ellis-Van Creveld[10]	Autosomal recessive	50

The terms common and uncommon are used in situations where the literature provides only approximations of risk.

*Case reports only in literature.

†Heterogeneous nature of diagnosis makes exact assignment of risk difficult. Some kindreds reported to have congenital heart disease in 25% of affected individuals.[57]

‡Congenital heart disease invariably present in complete form of disease, usually present as well in various formes fruste of the syndrome.

alies. They also noted that 24% of patients with coarctation of the aorta and 21% of those with ventricular septal defect had associated genitourinary anomalies.

In examining 453 infants with genitourinary malformations, Greenwood et al.[46] found congenital heart disease in 34 (8%). This association was especially prominent among the seven patients with bilateral renal agenesis, five of whom had congenital heart disease (71%). Two of these, however, had patent ductus arteriosus, which might be anticipated in a neonate with persistently high pulmonary arterial pressures and arterial hypoxemia due to concomitant pulmonary hypoplasia. Neonates with horseshoe kidney, a condition not yet diagnosed in utero, were found to have congenital heart disease in 44% of cases. No other associations between specific genitourinary and cardiovascular anomalies were apparent.

Skeletal system. Anomalies of the skeleton can be diagnosed in utero by ultrasound[47] and are often associated with cardiac anomalies. Greenwood et al.[12] found that 137 of 1566 infants (8.8%) identified as having congenital heart disease had associated skeletal abnormalities. Wallgren et al.[13] found such an association in 161 of 1000 children with congenital heart disease (16.1%), with an excess of tetralogy of Fallot (27% of affected infants). These figures are difficult to interpret, however, because of the heterogeneity of diagnoses represented.

Table IV provides information concerning skeletal dysplasias known to be associated with an increased risk of congenital heart disease. Some of these anomalies are quite rare, making the reports of associated cardiovascular abnormalities open to ascertainment bias. Further detail concerning the diagnostic criteria for the various syndromes may be found in sources devoted to the subject.[33, 48]

Genetic syndromes

Although many of the systemic associations we have mentioned above are inherited with recognized Mendelian patterns, there is another group of disorders that are conveniently described as genetic syndromes. We shall consider these in two groups: those related to chromosomal abnormalities and those inherited as syndromes with common patterns of abnormality but no grossly identifiable chromosome defect. From the latter group we have already considered those associated with skeletal dysplasias, as well as the Meckel-Gruber syndrome.

Chromosomal aberrations. A number of chromosomal defects are characteristically associated with congenital heart disease. Any list of such associations is necessarily incomplete as many autosomal abnormalities result in first-trimester spontaneous abortion, and accurate evaluation of cardiac structures, or primordia, is rarely undertaken. Table V presents relevant information about known associations between chromosomal abnormalities and congenital heart disease. It should be noted that each of the syndromes listed is accompanied by many additional somatic abnormalities, complete cataloging of which is beyond the scope of this report. For further details the interested reader is referred to texts dedicated to this subject.[10, 59]

Given the presence of a fetus with congenital heart disease, it is important to be aware that the risk of a coexistent chromosomal abnormality is approximately 5%.[10, 60] Since many of the phenotypic abnormalities associated with these anomalies are not detectable by ultrasound alone, an amniocentesis should be offered to all patients whose features have congenital heart disease.

Mendelian inheritance. The Noonan syndrome encompasses features of Turner syndrome (such as short

stature, characteristic facies, hypertelorism, webbed neck, and shield chest) but in the presence of a normal karyotype. These phenotypic features may not be diagnosable in utero; however, congenital heart disease is found in 50% to 55%,[10, 33] with right heart involvement in 80% of these, usually pulmonary valvular or infundibular stenosis. Asymmetric left ventricular free-wall hypertrophy may be seen[61] and should be amenable to diagnosis in utero, if present at the time of examination. Tetralogy of Fallot, Ebstein anomaly, ventricular and atrial septal defects, and total anomalous pulmonary venous return have also been described.[61, 62] As the syndrome is transmitted as autosomal dominant, couples at risk may request prenatal diagnostic testing, and fetal echocardiography may be useful.

Twin pregnancies

An excess of monozygotic twins has been noted in a retrospective review of congenital heart disease among offspring of multiple births. Anderson[63] looked at 107 children identified because of the presence of congenital heart disease in patients who were also twins. He found that of the 107 sets of twins, 67 were monozygotic (63%) and that there was a higher concordance rate for congenital heart disease among those judged to be monozygotic (6.8%) than among those judged to be dizygotic (2.2%; similar to the expected concordance rate for nontwin siblings). It is difficult to determine from this review whether the actual incidence of congenital heart disease is higher among twins than among singletons, but it would appear that of the overall population with congenital heart disease seen by Anderson, one of 63 cases were twins, which is in the same range as the frequency of twins in the general population. Schinzel et al.[64] identified a number of congenital anomalies that were more prevalent among monozygotic twins but did not include congenital heart disease.

There was a disproportionate number of monozygotic twins among the propositi of Anderson's population, leading him to conclude that there may be an increased tendency toward congenital heart disease among monozygotic twins.[63] Myrianthopoulos[65] reported that twins had a 17.5 per 1000 risk of congenital heart disease, as compared with 7.57 per 1000 among singletons. Although specific figures are not included, most of the increase was among monozygotic twins.

The rarest form of monozygotic twinning is conjoined twins, estimated to occur in from one per 30,000 to one per 100,000 pregnancies.[66] Of these, approximately 45% are either thoracopagus or thoracoomphalopagus twins, with omphalopagus representing another 10%. When the chest wall is shared, congenital heart disease is present in about 75%, and in most of the remainder the pericardium is shared.[67] The most frequent form of congenital heart disease is a conjoined heart with two ventricles and a varying number of atria, although a number of different permutations of numbers of atria and ventricles have been reported.[68] In virtually all, septal defects are present in addition to other deformities.[67] Even in those with omphalopagus and sharing no thoracic structures, congenital heart disease has been described in at least one of the twins in more than a quarter of twin pairs. It is interesting to note that only one of nine sets reported had concordance of the congenital heart disease in both twins.[69]

Another rare form of twinning is the development of acardia, estimated to occur in 1% of monozygotic twins, or one per 35,000 births. There appears to be a spectrum of disease ranging from the true acardius (holoacardius), in which no cardiac tissue is present, to the pseudoacardius, in which a rudimentary heart is present.[70] The parasitic twin may cause the heart of the normal twin to develop a volume-overload type of congestive heart failure, which has been successfully treated in utero with maternal digitalization.[71]

Drug-related malformations

A number of drugs have been implicated as the primary cause of various syndromes of congenital malformations, often including the heart. Now only of historic interest, thalidomide was primarily known for its association with phocomelia when ingested in the first trimester. If the exposure was between days 20 and 36 after conception, a 5% to 10% incidence of congenital heart disease has been identified, especially tetralogy of Fallot, truncus arteriosus, and septal defects.[72]

The fetal alcohol syndrome, consisting of mental retardation, microcephaly, intrauterine growth retardation, hypertelorism with other facial abnormalities, and joint anomalies, has usually been seen in women consuming >60 ml of absolute alcohol per day, but more moderate alcohol consumption may carry some risk as well.[59] Congenital heart disease has been identified in 25% to 30% of infants with the full syndrome, especially ventricular and atrial septal defects.[72-74] While the joint anomalies and facial abnormalities, such as the hypoplastic philtrum, may be difficult to identify by ultrasound, some of the others, such as intrauterine growth retardation, microcephaly, hypertelorism, and cleft lip, could be recognized.

Approximately 0.5% of pregnant women have epilepsy,[59] so the obstetrician is often faced with women who require anticonvulsants during the period of organogenesis. All studies of the potential teratogenicity of anticonvulsants are hampered by the unknown effect of untreated maternal epilepsy on development. The lack of association between phenobarbital and any malformation syndromes, however, speaks for a relatively small contribution, if any, from the maternal disease. One study[75] of the effects of phenytoin has suggested that women treated sporadically in the first trimester,

or only in the latter two trimesters, had a rate of malformation (about 30 per 1000) intermediate to that of those with no disease (24 per 1000) and those treated throughout gestation (61 per 1000). Several other studies have compared untreated epileptic patients with the general population and found no difference in overall malformation rates.[76-78]

The fetal hydantoin syndrome includes growth retardation, microcephaly, hypertelorism, a short broad nose, and hypoplasia of the nails and distal phalanges. Congenital heart disease has been described in 2% to 3%, particularly ventricular septal defect, pulmonary stenosis, aortic stenosis, and coarctation of the aorta.[72]

Trimethadione is less commonly encountered, with the primary indication for its use being petit mal epilepsy. It has been reported to be associated with a high incidence of congenital heart disease, with as many as 15% to 30% of exposed fetuses found to have transposition of the great arteries, tetralogy of Fallot, or hypoplastic left heart. Other features of fetal exposure are craniofacial and genital abnormalities, as well as intrauterine growth retardation.[72, 79, 80]

Exposure of the fetus to sex steroid hormones as a cause of congenital heart disease has been a source of controversy in the literature. An association between maternal unspecified sex hormone use and multiple anomalies, including cardiovascular, skeletal, gastrointestinal, and genitourinary, was first suggested by Nora et al.[81, 82] Harlap et al.[83] and Levy et al.[84] found similar effects in larger cohorts of patients.

Combination oral contraceptives were suggested by Heinonen et al.[85] to cause an increase in the rate of congenital heart disease from 7.8 per 1000 in a control group to 21.6 per 1000 (an adjusted relative risk of 2.4). Estrogens alone were associated with an adjusted relative risk of 1.4 and progestins alone with an adjusted relative risk of 1.5, with a cumulative risk for these two agents alone or in combination of 2.1. No unusual patterns of congenital heart disease syndromes were noted in these prospectively collected data, although others have suggested a relative increase in conotruncal defects,[74] nor were associated extracardiac anomalies found. A similar relative risk of congenital heart disease was found in a retrospective study performed by Rothman et al.,[86] although again no pattern of specific malformations was found and the 90% confidence limits for the incremental risk were 1.0 to 2.1.

It has been suggested that progesterone derivatives are associated with limb reduction defects,[87] as well as other components of the VACTERL syndrome,[81, 88] although other investigators[89] have failed to reproduce these findings.

The data are somewhat contradictory, but a twofold increase in congenital heart disease appears to be present in fetuses exposed to combination oral contraceptives or sex steroid analogues.

The most recent addition to the list of possible cardiac teratogens is the vitamin A analogue isotretinoin (Accutane, Roche Laboratories). A survey conducted by the American Academy of Dermatology and the United States Food and Drug Administration found 35 instances of pregnancy exposure, with resultant spontaneous abortion or congenital anomalies in 29 (83%). Those with congenital anomalies had a consistent pattern of central nervous system anomalies, primarily hydrocephalus and posterior fossa cysts, along with micrognathia and abnormal ears. In addition, five of the 10 anomalous infants had congenital heart disease, especially septal defects and great artery abnormalities. Exact risks are hard to assign as the true number of exposed fetuses is unknown. Some bias is inevitable because of selective reporting, but the defects were remarkably similar between infants and similar as well to those abnormalities seen in experimental animals.[90]

Maternal metabolic diseases

There are two classical maternal diseases associated with an elevated risk of fetal anomalies, phenylketonuria and diabetes mellitus. In both, preconceptual counseling and strict control during early organogenesis, before most pregnancies are even clinically recognized, are essential in minimizing the risk of congenital malformations.

Patients with phenylketonuria may safely relax their dietary regimens in adolescence without adverse effects. It has recently become evident that hyperphenylalaninemia during organogenesis results in a number of malformations. Intrauterine growth retardation, microcephaly, and congenital heart disease are all prominent, and all appear in increasing frequency and higher maternal phenylalanine levels.[91] When maternal levels exceed 15 mg/dl, the frequency of congenital heart disease has been reported to be 12% to 16%.[92] Tetralogy of Fallot is disproportionately common among these children. It is important for phenylketonuric women to be aware of the small elevation in plasma phenylalanine that occurs after ingestion of aspartame (Nutrasweet, Searle Laboratories).[93]

The incidence of congenital heart disease is increased fivefold among infants of diabetic mothers.[94] The overall frequency of congenital anomalies has been related to first-trimester hemoglobin A_{1c} levels, an indicator of long-term glucose levels.[95] Ventricular septal defects and transposition of the great arteries are the most common forms of congenital heart disease among these infants. Hypertrophic cardiomyopathy may occur if control is poor in the latter part of gestation as well, although this may be expected to regress in the newborn period.[96] Other anomalies that may be detected by ultrasound include neural tube defects, renal anomalies, and the caudal regression syndrome.[97]

Table V. Congenital heart disease and chromosomal syndromes

Chromosomal aberration	*Live-born incidence*	*Congenital heart disease incidence (%)*	*Typical lesions*
Trisomy 21 (Down)	1/800	50	VSD, CAVC
Trisomy 18 (Edward)	1/8,000	99	VSD, CAVC, DORV
Trisomy 13 (Patau)	1/20,000	90	VSD
Trisomy 8	Rare*	50	VSD
Trisomy 22	Rare	67	ASD
Trisomy 22†	Rare	40	TAPVR
Trisomy 9	Rare	>50	VSD
45, X (Turner)	1/5,000	35	Coarct, Bic AOV
5p- (Cri Du Chat)	1/20,000	20	VSD
4p- (Wolf)	Rare	40	ASD
13q-	Rare	25	VSD
+14q-‡	Rare	>50	PDA
18q-	Rare	<50	VSD
XXXXY	Rare	14	PDA§
Triploidy	Rare	‖	VSD

Adapted from Nora and Nora[10] and Simpson et al.[59]

VSD = Ventricular septal defect; CAVC = complete atrioventricular canal; DORV = double outlet right ventricle; ASD = atrial septal defect; TAPVR = total anomalous pulmonary venous return; Coarct = coarctation of the aorta; Bic Aov = bicuspid aortic valve; PDA = patent ductus arteriosus.

*"Rare" means not detected among prospective live-born surveys. In these syndromes, incidence of congenital heart disease is based on case reports.

†Partial trisomy 22 (cat-eye syndrome).

‡Partial trisomy 14q.

§Significance is uncertain, as it represents one of six reported cases.[10]

‖Quite rare among live births, making assessment of congenital heart disease risk impossible.

Intrauterine infections

The classic example of viral teratogenesis is the rubella syndrome, which may include cataracts, deafness, and microcephaly in addition to congenital heart disease. Infection may cause abortion in up to 50% of fetuses infected in the first trimester and other effects in 70% of the remainder. Among those with congenital heart disease, patent ductus arteriosus is present in 58%, ventricular septal defect in 18%, tetralogy of Fallot in 7%, and pulmonic stenosis in 6%.[10, 59, 60] Although women inadvertently vaccinated during early gestation have been shown to have virus cultured from the products of conception at abortion,[98] no teratogenic effects of vaccination have been found.[99]

An association between certain enteroviruses and congenital heart disease was suggested in one study based on early and late pregnancy serologic testing, particularly coxsackieviruses B3 and B4.[100] Others have disputed these findings.[10]

Comment

We have reviewed associations between extracardiac congenital anomalies that may be identified with ultrasound and similarly identifiable cardiac malformations. When a nonfatal extracardiac malformation is identified, the presence of major structural heart disease will influence the long-term survival, and prior knowledge of its presence will permit optimal obstetric and neonatal management.

Fetal echocardiography has been successfully applied in the accurate evaluation of the structurally abnormal heart in a number of laboratories.[11, 101, 102] We feel that echocardiography should ideally be performed in all fetuses identified as having extracardiac malformations. At present, there are a limited number of laboratories with extensive experience in fetal echocardiography. Consultation with such centers may be advisable when anomalies known to have a high association with congenital heart disease are found.

Based on our review of the literature, we suggest that the anomalies found in Table IV represent those with a particularly high frequency of association with congenital heart disease. If such anomalies are identified in utero, fetal echocardiography should be sought, as the information obtained may have a significant impact on subsequent care. Future epidemiologic or clinical studies may result in modification of this list.

Fetal echocardiography can take another role in clarifying certain prenatal diagnoses. In a fetus with a high risk of a syndrome involving multiple systems due to genetic factors (for instance, family history of Noonan syndrome) or environmental exposures (for instance, maternal drugs, metabolic disorders, or infections), an abnormal fetal echocardiogram may provide a sentinel sign for other anomalies. When there are ambiguous anomalous findings in other systems (for instance, skeletal dysplasias) an abnormal fetal echocardiogram may assist in differential diagnosis.

Aneuploidies are known to carry a high risk of congenital heart disease (Table V). For many of the major

*Uniformly fatal; presence of congenital heart disease unrelated to prognosis.

†Possible relationship to congenital heart disease; firm association not established.

chromosomal aberrations (tetraploidies, trisomy 13, or trisomy 18), the presence of congenital heart disease has little impact on long-term prognosis. For others, such as Turner syndrome (45,X), fetal echocardiography may provide important information for parental counseling and perinatal care.

Our current protocol when performing fetal echocardiography for any indication is to establish that fetal growth parameters are normal for the anticipated gestational age and to survey the fetal anatomy. This includes identification of the stomach, kidneys, bladder, cerebral ventricles, integrity of the spine, placental position, and morphologic features and adequacy of amniotic fluid volume. For this reason our team includes both obstetricians and cardiologists.

When a cardiac malformation is diagnosed, formal Level II scanning is undertaken to examine these other structures in detail. Because of the 5% risk of chromosomal abnormality in fetuses with congenital heart disease, we offer genetic amniocentesis to all patients unless delivery is imminent.

Similarly, whenever an extracardiac anomaly is found in our Level II obstetric ultrasound facility, we perform fetal echocardiography (Table VI). Through this sort of patient surveillance we will maximize the identification of those patients with intercurrent problems. This, in turn, will enhance our ability to plan optimal perinatal and neonatal management.

Fetal microcirculation of abnormal human placenta

I. Scanning electron microscopy of placental vascular casts from small for gestational age fetus

Mary M. L. Lee, Ph.D., and Ming-neng Yeh, M.D.
New York, New York

The latex injection–corrosion cast technique coupled with scanning electron microscopy was applied to the study of small for gestational age placentas. The main ultrastructural changes observed in the fetal vasculature of small for gestational age placentas were less branching of arteries and veins, capillaries with variable diameters, and many capillary bud projections; also numerous "H"-shaped anastomoses were present in the capillary network. The corrosion/cast technique approach enabled us to visualize the three-dimensional distribution of arteries, veins, and capillary network as well as the ultrastructural alterations among the various-sized vessels in the abnormal placenta. Light microscopic examination of these placentas revealed numerous syncytial knots and fibrinoid deposits pressing on arteriolar and capillary vessels at different locations. We suggest that the numerous capillary buds and anastomoses are characteristics of neovascularization and may be a compensatory phenomenon of the capillary network. This information could shed new light on alterations of physiologic functions of the pathologic placenta. (AM J OBSTET GYNECOL 1986;154:1133-9.)

Key words: Fetal microcirculation, placenta, scanning electron microscopy, intrauterine growth retardation, neovascularization

Since the placenta is involved in the basic functions of metabolism, transfer of nutrients, exchange of gases, and endocrine secretion, it is essential for maintaining pregnancy and promoting normal embryonic-to-fetal development. An examination of the three-dimensional distribution and ultrastructural appearance of normal fetal placental vasculature helps in understanding these physiologic functions. The morphologic characteristics of fetal blood vessels in the human placenta have recently been examined by the latex injection–corrosion cast technique coupled with the scanning electron microscope.[1-3]

The latex injection–corrosion cast technique, when applied to the study of the pathologic small for gestational age (SGA) placenta, revealed new data on the ultrastructural appearance of abnormal fetal-placental vasculature. The purpose of the present study was to elucidate the ultrastructural changes in the fetal-placental vasculature that are present in the pathologic SGA placenta by scanning electron microscopy.

Material and methods

Seven human placentas from mothers who were delivered of SGA babies (less than tenth percentile in weight at birth) were used for the study (Table I). The same latex injection–corrosion cast technique used in the study of normal human placentas was applied to this investigation.[3] The umbilical cord was threaded by a small catheter in the umbilical artery and vein and provided a route of entrance for the injection medium and a route of egress. After catheterization, the placenta was suspended in water and then flushed with warm saline at 50 mm Hg injection pressure. This was followed by an injection of 70% Cementex (Cementex Corp., New York, NY 10013). After polymerization by air drying, the latex inside the blood vessel hardened into a vascular cast. For further hardening, tissue was left in 10% formalin for 2 weeks. Then the placental tissue was macerated by treatment with sodium hypochlorite. The resulting vascular cast was air dried and

teased into small pieces for examination by scanning electron microscopy. The details of the injection–corrosion cast technique have been described in previous articles.[3-5]

For examination by scanning electron microscopy, the casts were attached to aluminum stubs by silver conductive paint and then coated with gold-palladium in a Hummer I Sputterer (Anatech, Ltd., Alexandria, VA 22310). On completion of the preparations, the resulting vascular casts were viewed and photographed on a JEOL-25 scanning electron microscope at 15 kV and 0- to 45-degree tilt.

A small portion of placenta was removed for regular light microscopic examination. The placental tissue was put into formalin and remained there for 2 weeks before processing for light microscopy. The sections for

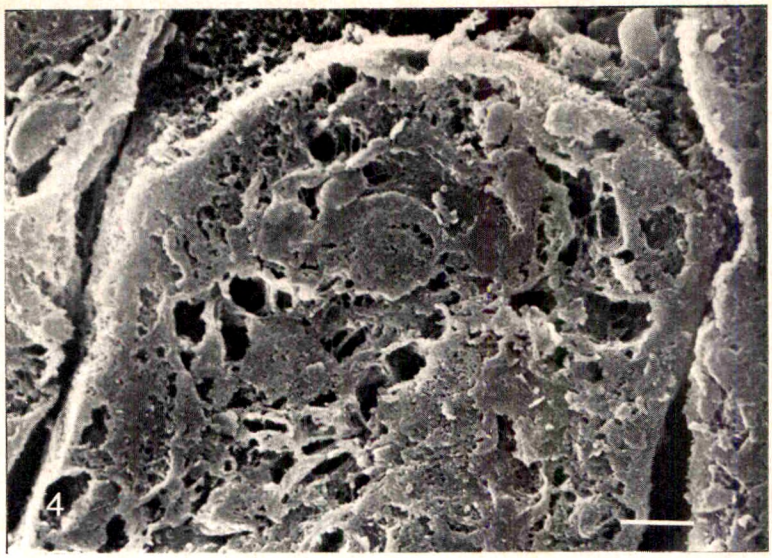

Fig. 4. An area of chorionic villi from an SGA placenta shows a number of capillaries that have compressed or occluded lumina. *Bar* = 10 μm.

light microscopy were cut at 8 μm and stained with hematoxylin and eosin for observation and photography.

Observations

Scanning electron microscopic observations of vascular casts from SGA placentas revealed the following alterations from normal morphologic features: the capillary network was more dense and contained many "H"-shaped anastomoses (Fig. 1 *a* and *b*); the capillaries were of variable diameters and contained numerous budding projections (Fig. 2); also less branching occurred among the arteries and veins than is found in normal human fetal-placental vessels (Fig. 3). Regarding the H-shaped capillary anastomoses, we found that they were numerous in the SGA placental microcirculation. The capillary network appeared more dense and more tortuous than that of the normal human placenta (Fig. 1, *a*). Furthermore, the number of fused loops was definitely increased over normal. While the number of capillary anastomoses increased, the amount of arterial and venous branching was decreased as compared with that of the normal placenta.

Scanning electron microscopy of whole-surface SGA placental tissue showed that large portions of the chorionic villi had occluded capillaries (Fig. 4) while a more normal-appearing villous capillary network area was seen elsewhere (Fig. 5). Also seen in the pathologic specimen were areas of fibrinoid-like material compressing portions of capillaries; many of the lumina of capillaries appeared collapsed or clogged. The umbilical cord from our SGA placenta was cut and processed for scanning electron microscopy. Fig. 6 shows a cross section of the cord with one patent umbilical vein and two umbilical arteries. One of the arteries is patent while the other has an occluded lumen; this was observed in two of the three umbilical cords.

Light microscopic observations of the pathologic placental tissue revealed that the chorionic villi had numerous syncytial knots (Fig. 7) on the villous surface. The cytotrophoblast was distinct while the syncytiotrophoblast was so thinly attenuated that it was not clearly seen. Fibrinoid deposits of variable size were observed around some villous capillaries. The villi themselves had a nonedematous appearance by light and scanning electron microscopy.

Comment

Vascular anatomy of the abnormal placenta with fetal growth retardation has been investigated by many researchers.[6-11] However, there have been no previous reports on vascular cast studies from abnormal placentas by scanning electron microscopy. This approach enabled us to visualize the three-dimensional distribution of arteries, veins, and capillary network in the pathologic placenta as well as the ultrastructural alterations among the various-sized vessels in the abnormal placenta. In addition, this approach could elucidate the alterations of the physiologic functions of the pathologic placenta.

Scanning electron microscopic analysis of fetal placental vascular casts revealed the following new findings: The capillaries have frequent H-shaped anastomoses and numerous forming vascular buds. Both phenomena are involved in neovascularization and may represent efforts by the abnormal placental capillary network to increase its density so that the fetus will have an increased capacity for exchange of nutrients and

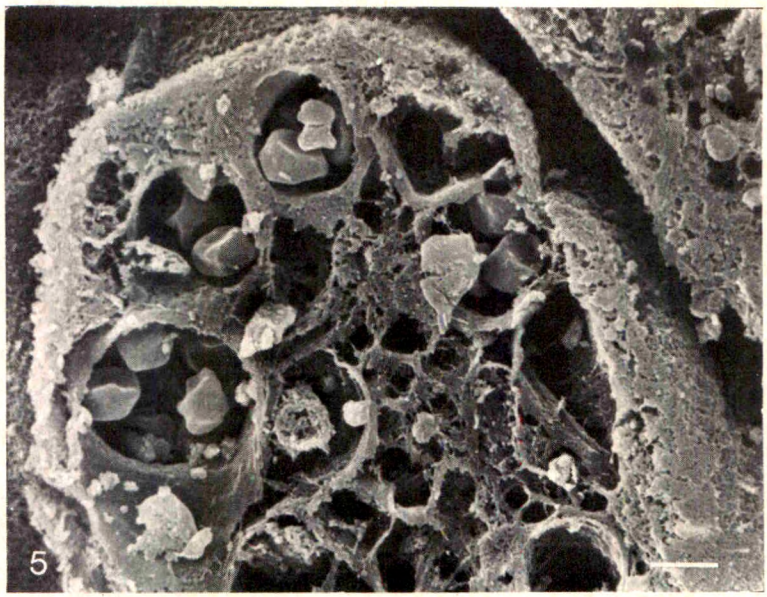

Fig. 5. A section of the chorionic villi from another portion of the SGA placenta showing a more normal-appearing cluster of capillaries with patent lumina, many of them filled with red blood cells. *Bar* = 10 μm.

gases at the capillary level. Neovascularization was similarly observed in vascular casts by scanning electron microscopy by Burger et al.[12] in the rat corneal capillary network after injury to the cornea by chemical cauterization. After 1 day, the injected vascular cast showed formation of new vascular buds from capillaries and venules. After a long time, microscopy of the casts revealed that a rich anastomosing capillary network had formed from the earlier vascular buds. The findings of Burger et al. are in conformity with our findings from placental capillary casts with regard to the frequent H-shaped anastomoses and frequent vascular bud formation. Although the placental type of neovascularization was not the result of chemical injury, it had a very similar ultrastructural appearance. The stimulus for the capillary neovascularization in a SGA placenta may be the initially reduced number of blood vessels in the placenta. This would impair nutrient and gaseous exchange for the developing fetus. Under this condition, an increase in the density of the capillary network would result in improving placental-fetal exchange. Presently we are working on an SGA animal model to explore this hypothesis.

From light microscopic examinations of these placentas, numerous syncytial knots and fibrinoid deposits (Kirby et al.[2]) were observed pressing on the arteriolar and capillary vessels in the chorionic villi. These findings may account for the variability of capillary diameters and some arteriolar constrictions as seen in the latex casts by scanning electron microscopy. The cause of the fibrinoid deposits is not yet fully understood, but McCormick et al.[13] and Fox[14] have suggested an immunologic source. Additional studies for further exploration of this possible mechanism may be warranted.

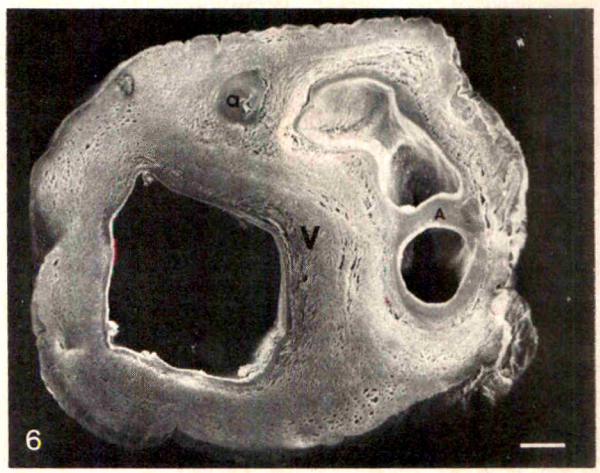

Fig. 6. Scanning electron micrograph of the umbilical cord from the placenta of an SGA fetus. The umbilical vein *(V)* is dilated, while one of the umbilical arteries *(A)* is patent and the other artery *(a)* is occluded. *Bar* = 1 mm.

Also seen by light microscopy were hyperplasia of the cytotrophoblastic cells and a thinly attenuated syncytiotrophoblastic layer. This finding confirms the light microscopic observations of Van Der Veen and Fox.[11] Normally at term the cytotrophoblast cannot be so clearly seen by light microscopy; such large, distinct cells probably represent highly active cells. Perhaps a genetic signal to these cells to reduce their functioning activity as term approached was lost or a time sequence of development was delayed. Another possibility is that

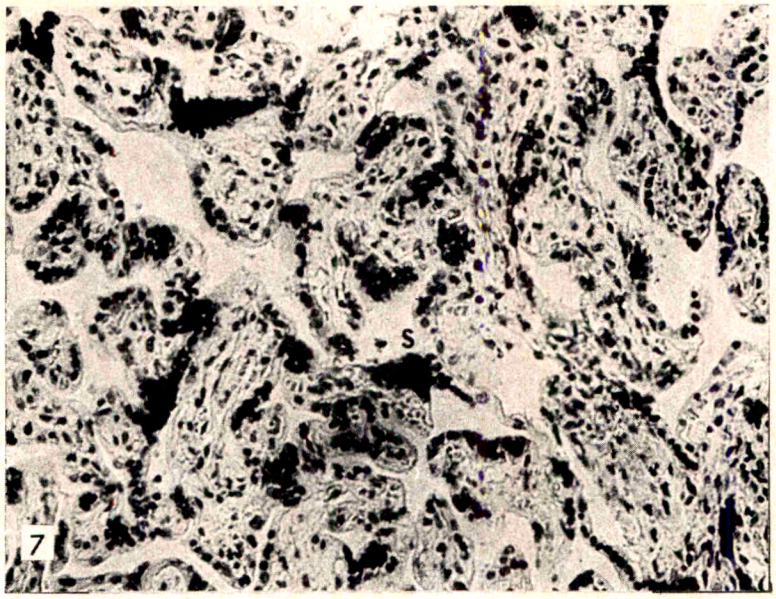

Fig. 7. Light micrograph of a section of the chorionic villi from an SGA placenta showing numerous syncytial knots *(S)* on the villi. The cytotrophoblast is distinct, while the syncytiotrophoblast layer is not clearly seen. (Hematoxylin and eosin. ×225.)

the hyperplasia of the cytotrophoblastic cells could be a compensatory repair mechanism. Reduced branching of the large vessels (arteries and veins) was also observed, which may indicate that there was an arrest of development during an early stage of placental blood vessel formation. With fewer large vessels, the volume of blood exchange to the growing fetus is decreased. The capillary network would thereby try to compensate by forming more capillaries to help increase the amount of surface area for nutrient and gaseous exchange. Our vascular casts of the term placenta of course cannot reveal the reason for a possible interruption of early development. We favor the concept that some event occurring early in blood vessel development caused alterations in the macrocirculation and microcirculation.

Cross section of the umbilical cord from an SGA placenta showed that while the umbilical vein appeared normal, the umbilical arteries had one patent and one occluded lumen. A possible explanation of this peculiar arrangement of one patent and one occluded umbilical artery is that there was a reduction of the amount of blood returning to the fetus, and the fetus became hypovolemic. As a consequence of this condition, both umbilical arteries cannot be maintained in the patent condition.

Our present scanning electron microscopic observations of latex casts provide an ultrastructural description of the alterations seen in the pathologic placentas, and light microscopy done in parallel supports the scanning electron microscope observations. In the future, transmission electron microscopy of specific vascular areas of the pathologic placentas will provide further ultrastructural data on the changes already observed by the other microscopic techniques.

We wish to thank Dr. Shu Chien, Department of Physiology, for the kind use of his laboratory facilities for this study. We also thank Honor O'Sullivan and Gerard Norwich for their fine technical assistance.

Fetal microcirculation of abnormal human placenta

II. Scanning electron microscopy of placental vascular casts from fetus with severe erythroblastosis fetalis

Mary M. L. Lee, Ph.D., and Ming-neng Yeh, M.D.
New York, New York

The latex injection–corrosion cast technique coupled with scanning electron microscopy was applied to the study of severe Rh sensitization of the placenta. The main observed ultrastructural changes in fetal vasculature in this type of placenta were very similar to those of the small for gestational age placenta; large-sized vessels exhibited less branching than those of the normal placenta, and the capillary network showed numerous vascular buds and "H"-shaped anastomoses. In addition, in Rh-sensitized placentas, the capillary network was remarkably sparse, and the cast also revealed smooth-surfaced veins with distinct U shapes undulating through the placental stroma. These U-shaped veins may be the result of umbilical flow impedance with subsequent umbilical venous hypertension, which stretches the veins into undulating form. (Am J Obstet Gynecol 1986;154:1139-46.)

Key words: Fetal microcirculation, placenta, scanning electron microscopy, Rh sensitization, neovascularization

The latex injection–corrosion cast technique coupled with scanning electron microscopy enables investigators to examine vascular casts from normal[1, 2] and abnormal human placentas in a three-dimensional form and to observe the ultrastructural changes in the fetal-placental vasculature. Several investigators[4-7] have described, using light and transmission electron microscopy, the appearance of Rh-incompatible placentas. In part one data were presented on ultrastructural changes observed in vascular casts from the placentas of small for gestational age fetuses.[3] This article will describe the vascular alterations that occurred in the placentas of fetuses with severe erythroblastosis fetalis and will discuss possible effects on the fetal-placental microcirculation resulting from such changes. To date, there has not been a scanning electron microscopic analysis of corrosion casts from Rh-incompatible placentas.

Material and methods

Four placentas from Rh-sensitized mothers who had given birth to babies with severe anemia were used for the study (Table I). The same latex injection–corrosion cast technique used in the normal human placenta was applied to this investigation.[2] The umbilical cord was threaded by a small catheter into the umbilical artery and vein, providing a route of entrance of injection medium and a route of egress. After catheterization, the placenta was suspended in water, flushed with warm saline solution at an injection pressure of 50 mm Hg, and followed by an injection of 70% Cementex (Cementex Corp., New York, NY 10013). After polymerization by air drying, the latex inside the blood vessel hardened into a vascular cast. For further hardening the tissue was left in 10% formalin for 2 weeks. Then the placenta was macerated by treatment with sodium hypochlorite. The resulting vascular cast was air dried and teased into small pieces for examination in the scanning electron microscope as previously described.[2, 8]

For scanning electron microscopic examination, the casts were attached onto aluminum stubs by silver conductive paint and then coated with gold-palladium in

a Hummer I Sputterer (Anatech, Ltd., Alexandria, VA 22310). On completion of the preparations, the resulting vascular casts were viewed and photographed on a JEOL-25 scanning electron microscope at 15 kV and 0- to 45-degree tilt.

A small portion of placenta was set aside for routine light microscopic examination. The placental tissue was put into formalin and remained there for 2 weeks before processing for light microscopy. The sections for light microscopy were cut at 8 μm and stained with hematoxylin and eosin for observation and photography.

Observations

Scanning electron microscopic observations of vascular casts from severe Rh-sensitized placentas showed that there was less branching of the large vessels than normal and that the capillary network was sparse (Fig. 1, *a* and *b*). The capillary cast also revealed scattered capillary constrictions, H-shaped anastomoses, and capillary budding (Fig. 2). There were also abrupt constrictions seen in capillaries as well as in arteriolar vessels (Figs. 3 and 4). The casts also revealed various-sized vessels forming tortuous U-shaped loops that course through the placental tissue. From the smooth

surface, it is deduced that the U-shaped vessels are veins and venules (Fig. 5, *a* and *b*). Although only four Rh-incompatible placentas were examined for this study, the vascular casts as examined by scanning electron microscopy had a reproducible appearance.

Scanning electron microscopy of whole-surface Rh-sensitized placental sections showed that large portions of the chorionic villi had occluded or collapsed capillary vessels (Fig. 6, *A*). Many of the villi appeared to be filled with fibrous tissue rather than with patent blood vessels. There were, however, some areas in which the chorionic villi had a more normal appearance (Fig. 6, *B*). In these regions, the capillaries were patent and did not have occlusions of the lumina or fibrinoid deposits. The umbilical cord was cut and processed for scanning electron microscopy. Fig. 7 is a cross section of the cord showing a dilated umbilical vein filled with the injection medium and two arteries, each with a constricted lumen.

Light microscopic observations of this pathologic tissue showed areas of histologic abnormalities as well as areas with more normal chorionic villi. A variability in microscopic appearance of chorionic villi from the same placenta occurred often. Also the villi in some regions had stromal edema with little to no space between them; in other regions, distinct intervillous spaces were seen (Fig. 8, *a* and *b*). The villi also had some areas that contained very few capillaries, giving these villi an immature appearance at term. These groups of immature villi were scattered throughout the placenta. The syncytiotrophoblast appeared normal for term, but the cytotrophoblastic cells were large and distinct.

Fig. 3. An area of loosely packed capillaries. An abrupt constriction is seen in one of the capillary vessels *(arrow)*. *Bar* = 10 μm.

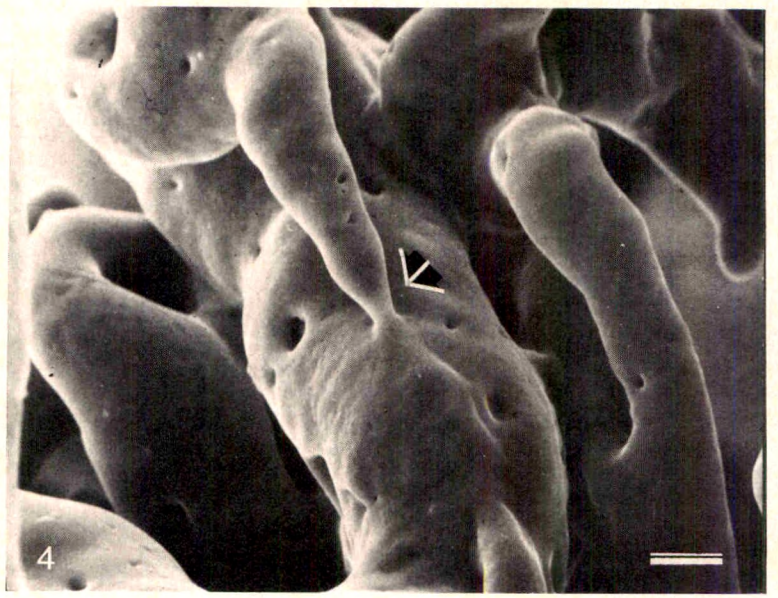

Fig. 4. Vascular cast of an arterial vessel with an abrupt constriction of one of its branches *(arrow)*. *Bar* = 10 μm.

Comment

Our scanning and light microscopic observations of Rh-sensitized placentas are in support of previous investigators' findings of variability in appearance of chorionic villi, some with edema and some with a normal appearance. Also some villi had very few capillaries and presented an immature appearance at term.[4-6, 9]

In this study we examined the fetal microcirculation of placentas in cases of severe erythroblastosis fetalis. Scanning electron microscopic examination of the latex corrosion casts provided new information on the vasculature by showing, in three dimensions, that the large vessels (arteries and veins) had less branching than those from normal placentas and that there were many areas where the capillary network was sparse. The capillary casts also revealed that there were numerous constrictions and H-shape anastomoses as well as capillary budding. This neovascularization has been observed in placental casts from small for gestational age fetuses. A similar type of capillary budding was observed by Burger et al.[10] in rat corneal capillary casts after chemical cauterization. A possible reason for the placental

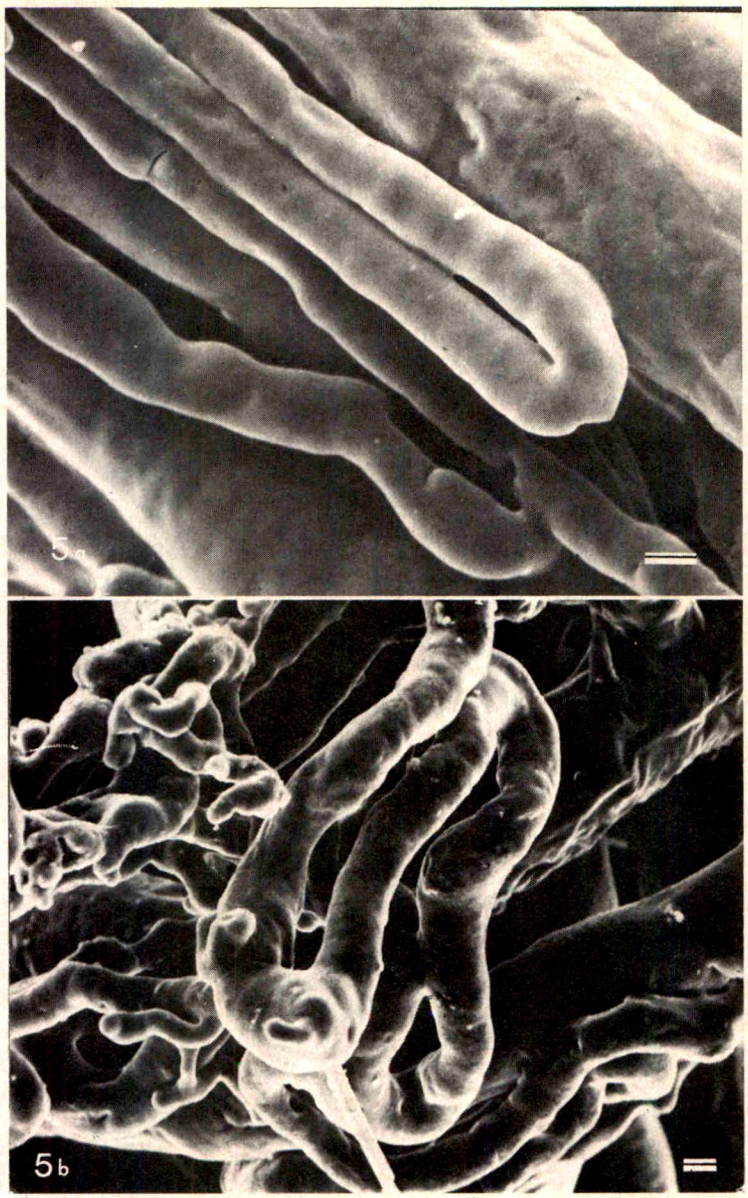

Fig. 5. *a*, Vascular cast of venule exhibiting the U-shaped appearance of one of its loops. The venules have a smooth surface. *Bar* = 10 μm. *b*, Vascular cast of a smooth-surfaced venule with three U-shape bends as it courses through the placental tissue. *Bar* = 10 μm.

capillary neovascularization is that there are insufficient capillary exchange surface areas for the developing fetus as the result of diminished villous vessels, similar to observations made in the SGA placental vasculature.[3] This reduction stimulates the capillaries to form new ones to augment the existing sparse network. The reason for a sparse capillary network in these placentas cannot be ascertained from corrosion cast examination; however, we speculate that there was some interruption in fetal-placental vasculature formation at a fairly early stage, resulting in reduction both of branching of large vessels and of density of the capillaries. The scattered arteriolar and capillary constrictions seen on the casts are probably due to areas of intracapillary erythropoiesis or to the presence of fibrinoid deposits pressing on the blood vessels, thus decreasing the vascular diameter.

Scanning electron microscopy of the vascular casts also revealed vessels of various diameters (20 to 100 μm), with distinct U-shaped turns, coursing through the placental tissue. From the smooth surfaces of these vessels, they appear to be venous structures. The U-shaped undulations of these vessels are remarkable in appearance; such structures were not observed in casts from normal human placentas or from SGA placentas. In all placentas, the injecting pressure was around 50

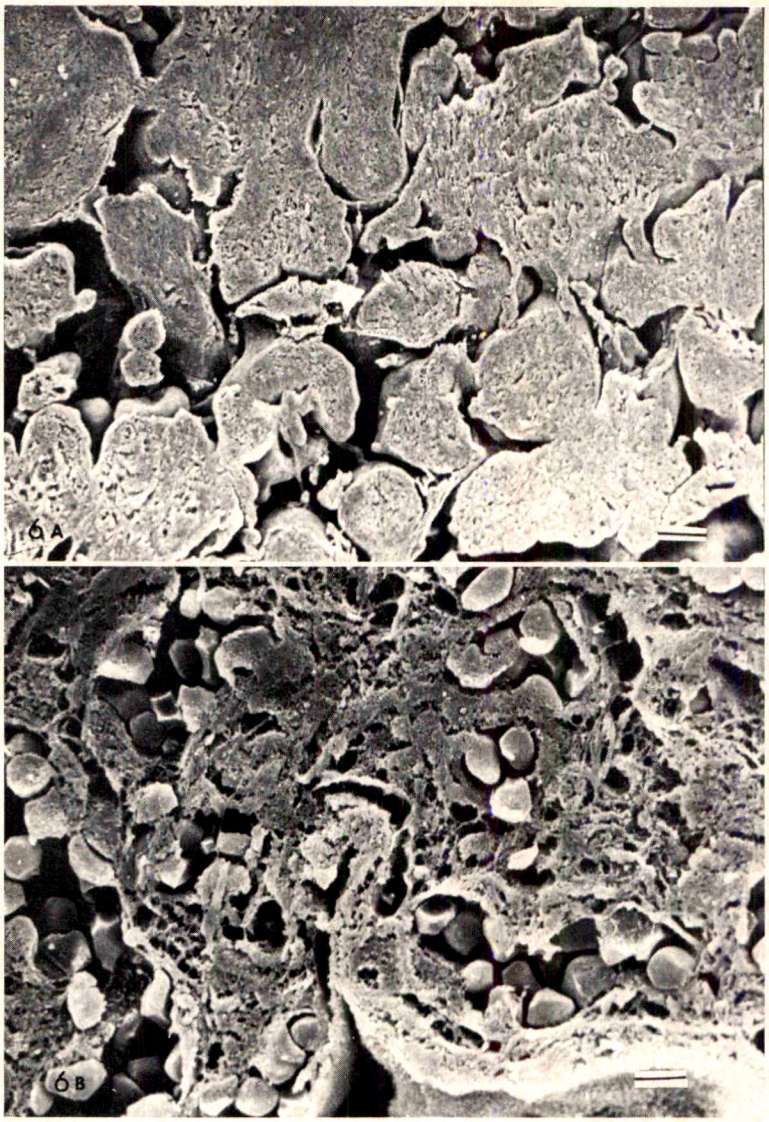

Fig. 6. *A*, A low-magnification electron micrograph of a section of the chorionic villi from the placenta of a fetus with erythroblastosis fetalis. Note that most of the capillaries are collapsed or occluded so that very few appear patent. *Bar* = 100 μm. *B*, A higher magnification of a section of the chorionic villi from the same placenta showing an area with a more normal appearance. The capillaries are patent in many areas. *Bar* = 10 μm.

mm Hg, slightly less than physiologic pressure. Therefore, the presence of U-shaped loops would indicate that the vessels existed in the living placenta under high pressure. In severe erythroblastosis fetalis, hepatosplenomegaly develops in the fetus, resulting in venous hypertension. This produces impedance in umbilical flow to the placenta. With pressure building up in the fetal-placental vessels, edema will result in the chorionic villi, with veins and venules becoming U-shaped loops under high pressure. Under this condition, the umbilical vein will become distended. This dilation was observed in the cross section of the umbilical cord from cases of severe erythroblastosis fetalis. From these scanning electron microscopic studies of the vascular morphologic features, we can better interpret the histologic findings and are also able to deduce the existing physiologic flow conditions in this abnormal placenta. Future examination of vascular casts from other types of abnormal placentas will provide additional information on fetal-placental microcirculation. Such ultrastructural data will be helpful to both placentologists and physicians.

We thank Dr. Shu Chien, Department of Physiology, for the kind use of his laboratory facilities for this study. We also thank Honor O'Sullivan and Gerard Norwich for their fine technical assistance.

Uterine metabolism of the pregnant rabbit under chronic steady-state conditions

Robert L. Johnson, M.D., Marc Gilbert, M.D., Stephen M. Block, M.D., and Frederick C. Battaglia, M.D.

Denver, Colorado

The study of uterine metabolism in pregnancy under chronic steady-state conditions has been confined to large mammals and, more recently, to the guinea pig. The pregnant rabbit is of interest because of its short gestation and large litter size. We developed an indirect approach involving retrograde catheterization of the uterine venous drainage, permitting measurement of both uterine metabolic quotients and uterine uptakes. Radioactive microspheres were used to measure blood flow. A large lactate and ammonia efflux from the uterus was found. In the fed state, ketogenic substrates were taken up in small amounts. However, during starvation a significant increase in ketoacid uptake was observed with a concurrent fall in acetate uptake. There was a large glucose/oxygen quotient across the uterus, but the glucose plus lactate/oxygen quotient was comparable to that found in the sheep and guinea pig (0.6 ± 0.1). It is apparent that in all three species studied under chronic steady-state conditions (sheep, guinea pig, and rabbit) there is a large glucose uptake associated with a net lactate producton, and fuels other than glucose and lactate must be used by the uterus. (Am J Obstet Gynecol 1986;154: 1146-51.)

Key words: Uterine metabolism, uterine metabolic quotients, ammonia and lactate production, glucose and lactate quotients, placental metabolism

The metabolic demands of the developing conceptus remain an important area of interest in mammalian reproductive physiology. Metabolic requirements of pregnancy have previously been described in large mammals[1] and, more recently in our laboratory, in the guinea pig.[2] Among mammals, the variations of litter size, maturation, tissue composition, and maternal caloric requirements preclude simple interspecies comparisons. Studies in conscious, unstressed sheep,[1] cow,[3] and guinea pigs[2] have described glucose as the major oxidative substrate of the uterus. A net lactate efflux from the uterus has also been described in all three species.[2-5]

There have been few studies in small mammals carried out under chronic steady-state conditions. Recently, our laboratories have reported data on the cardiac output and uterine blood flow of the pregnant rabbit under chronic steady-state conditions, a study which involved catheterization of the arterial and peripheral venous circulations.[6] We now report successful chronic catheterization of the uterine venous drainage, permitting studies of oxygen and substrate uptake by the gravid uterus under steady-state conditions.

Material and methods

Ten New Zealand White rabbits were artificially inseminated permitting precise pregnancy dating (within 1 day). During the last half of gestation, the animals were anesthetized with ketamine hydrochloride, 50 to 150 mg intramuscularly (Parke Davis & Co.), and

xylazine hydrochloride, 25 to 50 mg intramuscular (Bayes). Polyvinyl catheters were placed in the left ventricle (0.34 mm inner diameter) and distal aorta (0.23 mm inner diameter). A closed-end nylon catheter (0.34 mm outer diameter and 0.23 mm inner diameter) was placed in the left uterine vein by a retrograde technique. The retrograde catheterization of the uterine vein was carried out as follows. The catheter was inserted into the femoral vein and advanced to the junction of the common iliacs. Under direct visualization the inferior vena cava was occluded transiently so that the catheter would advance up the uterine vein. The position of the catheter tip was confirmed by direct palpation. By this approach, the uterus need not be manipulated at all and the catheter can be positioned to sample drainage from an entire uterine horn.

All catheters were secured with sutures and surgical adhesive (Eastman 910) tunneled subcutaneously to an area between the scapulas and secured in a fixed plastic cap as previously described.[7] The catheters were maintained patent by flushing daily with a heparin-saline solution (200 units/ml). The animals were given food and water as needed and postoperative food intake was measured. All animals were studied on two consecutive days after a 3-day recovery period.

Paired arterial and venous samples were drawn simultaneously for oxygen, glucose, lactate, acetate, β-hydroxybutyrate, acetoacetate, and ammonia determinations. Four sets of such samples were obtained during approximately 1 hour, and the mean arteriovenous difference for each substrate was used as the value for that day of study. After completion of sampling on the second day of study, all animals underwent injection with radioactive "carbonized" microspheres (tin 113, 24 μ in diameter) with the use of the integrated withdrawal technique previously described.[8] The animals were put to death and the uterus of each dissected to determine fetal, placental, and uterine weights. Ovaries, kidneys, and adrenals were dissected to verify paired organ flows. The calculations for uterine blood flows were done by the reference sample method.[8]

Two groups of animals were studied, those with dietary intakes of >45 gm/day (previously found to be the lower limit of normal food intake)[9] and a second group of starved animals with dietary intake <20 gm/day.

Chemical methods. All metabolic uptakes for oxygen and substrates across the uterine horn were calculated by application of the Fick principle. Oxygen content was measured with an OSM_2 hemoximeter (Radiometer). The hemoximeter has the advantage of giving highly reproducible measurements of both hemoglobin (in millimoles per liter) and oxygen saturation, from

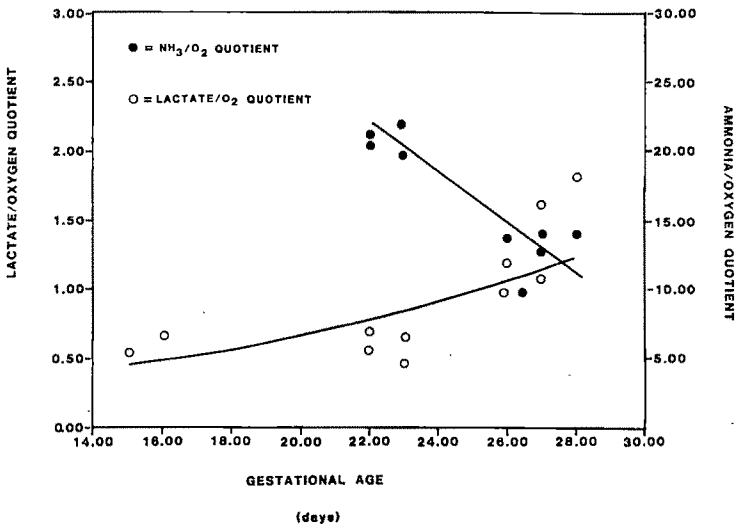

Fig. 1. Gestational changes in lactate/oxygen and ammonia/oxygen quotients across the uterus.

which the oxygen content is calculated. Glucose, lactate, acetate, acetoacetate, and β-hydroxybutyrate levels were measured with standard enzymatic methods.[10] The ammonia content was determined according to the ion-exchange method of Kurahasi et al.[11] The samples were measured in triplicate with a coefficient of variation of 4%.

The average arteriovenous concentration differences of the four sets of measurements were calculated by taking into account each nutrient used to ascertain the metabolic quotients for that day's study with the formula:

$$\frac{\text{Average arteriovenous difference of substrate (mmol)} \times k}{\text{Average arteriovenous difference of oxygen (mmol)}}$$

where k is the number of oxygen molecules required for the complete oxidative combustion of one molecule of the substrate. This number varies from two for acetate to six for glucose. The mean of the four arteriovenous differences was also used to calculate the coefficient of extraction with the following formula:

$$\frac{\text{Arteriovenous} \times 100\ (\%)}{\text{Arterial concentration}}$$

Statistical methods used were either paired or unpaired *t* tests, as designated. Regression lines were calculated by the least-squares method. All values are expressed as mean ± SEM unless otherwise noted. The significance of correlation coefficients was calculated by use of hypothesis testing.

Results

Table I presents a summary of maternal weights, gestational age, fetal and placental weights, and uterine blood flows for the entire uterus as well as for the individual uterine horn studied. The studies covered a gestational age range of 15 to 28 days.

Table II presents a summary of all metabolic data including mean arteriovenous differences and uterine uptakes or production of substrates in the horn studied. The mean arteriovenous glucose difference was 0.95 ± 0.82 μmol/ml, the oxygen difference was 3.89 ± 0.21 μmol/ml, and the lactate arteriovenous differences was −1.15 ± 0.12 μmol/ml. Small positive arteriovenous differences for ketoacids and acetate were found but did not approach statistical significance.

Expressed per kilogram of tissue (uterus plus placenta plus fetus), the rabbit uterus and its contents consumed 125.58 ± 8.49 μmol/min of glucose, 532.58 ± 38.83 μmol/min of oxygen, and 11.78 ± 2.50 μmol/min of acetate as well as small amounts of ketoacids. There was a large efflux of lactate (−151.77 ± 11.77 μmol/min) and of ammonia (9.15 ± 1.06 μmol/min) from the uterus.

Table III presents a summary of the metabolic quotients. The glucose/oxygen quotient was 1.46 ± 0.11, and the lactate/oxygen quotient was −0.91 ± 0.09. The glucose plus lactate/oxygen quotient was 0.55 ± 0.064. The ketoacid/oxygen quotients were 0.04 ± 0.01 for β-hydroxybutyrate and 0.02 ± 0.004 for acetoacetate. Acetate/oxygen quotient was 0.04 ± 0.009. The sum of all substrate quotients was 0.65 ± 0.015.

Since ammonia and lactate are both small molecules, which we believe are produced within the placenta, it was of interest to compare the quotients at different stages of gestation. Fig. 1 illustrates the fact that these quotients do not show a similar pattern of change. The ammonia/oxygen quotient falls while the lactate/oxygen quotient rises with increasing gestational age.

Table IV compares two groups of animals, one con-

suming a normal quantity of food and a subgroup of starved animals (animals offered food but with decreased dietary intake). Previous observations by Gilbert et al.[9] defined an adequate dietary intake as a minimum of 45 gm/day. The gestational age and litter size were similar in the two groups. The total uterine weight was slightly decreased in the starved group (153.58 ± 33 gm in fed animals versus 120.20 ± 5.46 gm in starved animals), although this difference is not statistically significant.

Fig. 2 presents a comparison of uptakes per kilogram of left uterine horn (mean ± SEM) with uptakes in starved animals presented as a percentage of the uptakes in fed animals. The most dramatic change was in acetate uptake, which decreased 98%. Conversely, β-hydroxybutyrate and acetoacetate uptakes increased 300% and 200%, respectively. Fig. 3 demonstrates that there was an inverse relationship between uterine ketoacid uptake and daily food intake.

Fig. 4 presents a comparison of the production rates for lactate and ammonia in starved animals expressed as a percentage of the fed state across the left uterine horn. A significant 25% decrease in lactate production was found. The decrease in ammonia production was not significant.

Comment

This study presents data describing the metabolism of the rabbit uterus under chronic steady-state conditions. It should be emphasized that the surgical approach we have utilized for these studies differs from that of Gilbert et al.,[12] who recently reported metabolic data for the rabbit uterus. In the latter study, venous blood from a single fetoplacental unit and the surrounding myometrial tissue was sampled. Thus the metabolic quotients in that study reflected the metabolism of that unit. In our approach the retrograde catheterization can be achieved without any direct manipulation of the uterus or its contents and the catheter tip can be directly localized in the main venous drainage of the horn. However, it is encouraging that the two different approaches have yielded very similar estimates of glucose uptake and lactate production by the pregnant rabbit uterus, 127.5 versus 125.6 μmol/L glucose/min/kg in the study of Gilbert et al.[12] versus the present study and 122 versus 151.8 μmol/L lactate/min/

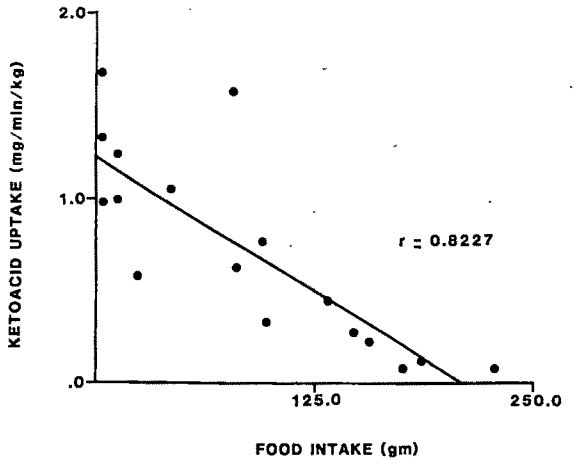

Fig. 3. Maternal food intake (grams) versus uterine ketoacid uptake (milligrams per minute per kilogram).

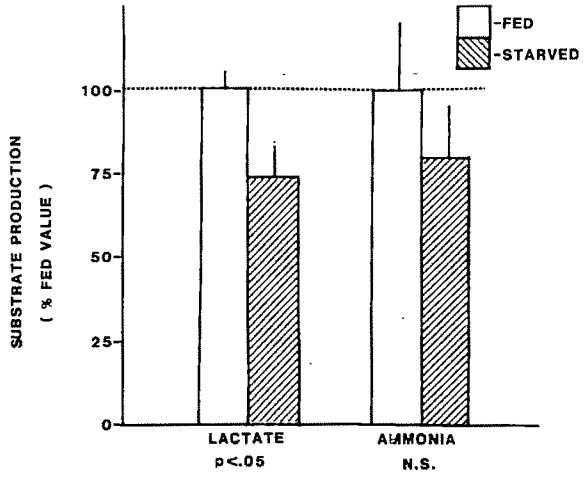

Fig. 4. Comparison of lactate and ammonia efflux from the left uterine horn in fed and starved states.

Table V. Comparison of chronic metabolic studies of three species in our laboratory

Species	*Gestation (%)*	*Glucose/oxygen quotient*	*Lactate/oxygen quotient*	*(Glucose + lactate)/ oxygen quotient*	*Coefficient of extraction (%)*	
					Glucose	*Oxygen*
Rabbit	70-95	1.5 ± 0.1	−0.9 ± 0.1	0.6 ± 0.1	19.8 ± 1.7	53.0 ± 3.3
Guinea pig	60-75	1.2 ± 0.1	−0.5 ± 0.1	0.7 ± 0.1	11.9 ± 1.3	39.0 ± 2.8
Sheep	80-95	0.8 ± 0.1	−0.1 ± 0.0	0.7 ± 0.1	9.0 ± 0.6	24.2 ± 1.1

Values are mean ± SEM.

kg, respectively. Our laboratory has previously presented the results of studies on the metabolism of sheep[1, 4, 5] and guinea pig uteri.[2] Coupled with the similar studies of Comline and Silver[3, 13] on horse and cow uteri, five mammalian species have now been studied under comparable steady-state conditions.

In all five mammalian species studied thus far, uterine metabolism has been characterized by a very large glucose/oxygen quotient across the uterine circulation, reflecting the high rate of lactate production within the placenta. Table V presents the glucose plus lactate/oxygen quotients for the three species in which complete data are available. The quotients are significantly <1.0 and, in fact, are strikingly similar among the three species, which otherwise differ in a variety of important ways. In contrast, the coefficients of extraction for glucose and oxygen are quite different among these species, reflecting differences in perfusion of the uterus relative to its metabolic rate with the three species.

Another characteristic of uterine metabolism that is true in the rabbit, as in other species, is the efflux of ammonia. In the sheep it has been possible to demonstrate that the uteroplacental tissues are the source of the ammonia, not the fetal tissues. This was achieved by demonstrating that there was a significant entry of ammonia into both the umbilical circulation and the uterine circulation.[14] Since the umbilical circulation or fetal side of the placenta cannot be studied chronically in the rabbit, it is possible to demonstrate only that ammonia is produced within the uterus as a whole and represents a significant efflux of nitrogen from the pregnant uterus.

During gestation the uterine oxygen quotients for ammonia and lactate do not show a similar pattern of change. This observation suggests that these changes are not simply a reflection of changes in the proportion of placental tissue to total uterine contents, because, in the latter case, both quotients would show a similar pattern of change. Presumably, these changes must reflect a basic change in metabolism of the placenta with an increasing lactate production and decreasing ammonia production relative to the metabolic rate of the uterus.

In summary, 10 pregnant rabbits were chronically catheterized during the last half of pregnancy. Catheters were placed in the left ventricle and the distal aorta and into the main venous drainage from one pregnant uterine horn. Metabolic quotients across the uterus were measured for glucose, lactate, ketoacids, acetate and ammonia. In addition, uterine blood flow was measured by the integrated reference sample technique and microspheres 25 μm in diameter. A large lactate and ammonia efflux from the uterus was found. The glucose plus lactate/oxygen quotient was 0.6 ± 0.1.

There was a small but significant uptake of ketoacids and acetate by the uterus with the animals in the fed state. Ketoacid uptake increased and glucose and acetate uptake markedly decreased when maternal food intake was reduced. These uterine metabolic data collected under chronic steady-state conditions were compared with data collected under similar conditions for the sheep and guinea pig. While the coefficients of extraction differ among the species, the glucose plus lactate/oxygen quotients are remarkably similar for the uteri of all three species.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Maternal ovine placental vascular responses to adenosine

Megan Landauer, M.D., Terrance M. Phernetton, B.S., and John H. G. Rankin, Ph.D.
Madison, Wisconsin

We have examined the effect of adenosine given via retrograde uterine artery catheter at 25 mg/min to nine chronically catheterized near-term sheep pretreated with angiotensin II, 5 μg/min, via the jugular vein. Blood flows were measured by the microsphere technique. Flows were measured at rest, after 10 minutes of angiotensin II infusion, and after 1.5 minute of adenosine infusion. Blood pressure increased with angiotensin II infusion from 101 ± 2.63 to 130 ± 4.33 mm Hg ($p < 0.05$) and then remained unchanged with local adenosine infusion at 129 ± 4.33 mm Hg (NS). Organ resistances were:

Tissue	*Control*	*Angiotensin II*	*Adenosine*
Uterine resistance/gm	299 ± 0.04	767 ± 83 ($p < 0.05$)	355 ± 37.7 ($p < 0.05$)
Cotyledonary resistance/gm	37.9 ± 4.83	48.1 ± 4.93 ($p < 0.05$)	50.10 ± 5.27 ($p < 0.05$)

The experimental uterine tissue resistance increased with angiotensin II and showed vasodilation in response to adenosine. The cotyledonary resistance increased with angiotensin II infusion but showed no change in response to adenosine. The maternal-placental response was anomalous. Angiotensin II–induced maternal-placental vasoconstriction cannot be opposed by the exogenous administration of adenosine. (Am J Obstet Gynecol 1986;154:1152-5.)

Key words: Fetus, adenosine, angiotensin II, placenta, microspheres, blood flow

The factors that regulate maternal-placental blood flow are not fully understood. For example, we originally demonstrated that prostacyclin, which is a potent vasodilator,[1-3] is not effective in dilating the placental vasculature in the ewe. The systemic administration of prostacyclin via the jugular vein to a resting, unanesthetized sheep did not cause placental vasodilation.[3] In an attempt to avoid the systemic responses to prostacyclin we then applied the substance locally via retrograde uterine arterial catheter and again observed no dilation of the placental vascular bed.[1] In a third series prostacyclin was administered in the near-term sheep in association with angiotensin II in order to provide a vascular bed that had some vasodilatory reserve, and yet we still observed no vasodilation with prostacyclin.[2] An explanation for this anomalous result would be either that the sheep placenta was unresponsive to prostacyclin specifically or that this vascular bed was not responsive to other vasodilators. We therefore performed a series of experiments with adenosine used as the vasodilator.

Material and methods

Nine chronically catheterized near-term mixed breed ewes were used. Maternal drug administration was by jugular vein for angiotensin II and retrograde uterine artery catheter for adenosine. The uterine tissue not served by the cannulated artery was used for comparison as were the renal tissues.

Surgical procedure. All procedures were performed with the animal anesthetized by intramuscular ketamine (10 mg) and intravenous ketamine (10 mg/ml) and supplemental Nembutal as necessary. Animals were fasted for 48 hours and water was withheld for 24 hours before operation. The maternal jugular vein, left ventricle, and femoral arteries were catheterized. A ventral midline incision was made and the uterine vasculature exposed. The middle uterine artery was dissected free and a catheter passed in retrograde fashion to the branch point of the artery. The smaller of the two branches was chosen for catheterization. The peritoneum was oversewn and the catheter anchored to the uterus. All catheters were brought out via a subcutaneous tunnel and placed in a pouch on the flank. The abdominal incision was closed. The ewes were given an intramuscular injection of penicillin immediately after operation. Details of the surgical methods have been published previously.[1, 4, 5]

Flow measurements. For measurement of organ flows microspheres were injected in the left ventricle while blood was withdrawn from the femoral artery at 4.2 ml/min during and for 2 minutes after the micro-

Table I. Blood pressures, blood flows, and resistances of uterine and cotyledonary tissue downstream from retrograde catheter and of renal tissue

*$p < 0.05$ compared with preceding value.

sphere bolus injecton. Spheres were 15 μm in diameter and labelled with either cerium 141, strontium 85, iodine 125 or scandium 46. The spheres were suspended in 10% dextran in normal saline solution and consisted of 15 μCi of radioactivity in 0.4 ml. Each injection consisted of approximately 2.5×10^6 microspheres.

Experimental procedures. Experiments were performed 4 days after operation. The ewe was allowed to acclimate to a stanchion for 2 hours on the morning of the experiment. Blood pressure and pulse were recorded continuously by a transducer placed at the level of the scapulohumeral joint and were obtained via a femoral artery catheter.

Blood flow was measured before infusions were begun for control flow determinations. Angiotensin II was infused at 5 μg/min into the jugular vein for 10 minutes and a repeat blood flow measurement was performed. Adenosine was then given via retrograde uterine artery catheter at 25 mg/min via pump, in addition to the continuing angiotensin II infusion. A final microsphere bolus was given after 1.5 minutes of angiotensin II plus adenosine administration and the final test blood flows were obtained. The ewe was put to death at the end of the experiment while green dye was infused into the retrograde catheter. We have used this technique extensively and the dye is distributed to those areas served by the cannulated artery. The dye is taken up by both uterus and cotyledons and serves to map the experimental tissues. Removal of the uterus and its contents and the kidneys was performed immediately by laparotomy. Experimental (green) tissues were separated from control (nondyed) tissues.

Measurement and tissue preparation. Tissues were processed immediately. Cotyledons were analyzed individually and sample aliquots taken of homogenized renal and uterine tissues. All samples were assayed with a Nuclear Chicago Model 1185, three-channel gamma counter. The height of the tissue in the bottle was <1 cm above the bottom of the sampling vial. Three isotopes were used and the sample stream was preceded by three standard vials with known numbers of spheres of each isotope embedded in wax, followed by the femoral artery withdrawal blood samples. The spillover of each isotope into the other channels was calculated from the standard vials. The number of spheres in each sample was determined after calculation of spillover, and blood flow per organ was calculated from the number of spheres per organ relative to the number of spheres in the withdrawal blood samples by use of previously described equations.[4] Results are expressed as mean ± SEM. Statistical analysis of control, angiotensin II, and angiotensin II plus adenosine flows and resistances was done by analysis of variance with a $p < 0.05$ significance level.

Results

The results are given in Table I. It can be seen that the maternal blood pressure increased significantly with angiotensin II infusion as would be expected. Blood pressure remained elevated during the local infusion of adenosine, which indicated that no major systemic responses to adenosine were present at the time the observation was made. The flow per gram of the experimental uterine tissue could be seen to decrease significantly during the angiotensin II infusion and then to increase significantly during the administration of adenosine. The resistance of this vascular bed increased with angiotensin II and decreased with adenosine. This is the classical response that would have been predicted from the established literature. The renal vascular bed showed vasoconstriction in response to angiotensin II and did not dilate in response to the local administration of adenosine to the uteroplacental vascular beds. This again supports the contention that at the time the third measurement was made there was little or no recirculation occurring. The nonexperimental uterine and cotyledonary tissues behaved as did the renal vascular bed, showing constriction in response to angiotensin II and no vasodilation in response to adenosine.

It is the response of the placental vascular bed that

is most important. It can be seen from the data in Table I that the blood flow to the placenta did not change during the infusion of angiotensin II. This is to be expected from the literature in that the combination of vasoconstriction and elevated blood pressure served to maintain the blood flow.[6] However, during the local administration of adenosine there was no increase in placental blood flow. This is the anomalous response. It can be seen that the vascular resistance increased with angiotensin II and thereafter did not change even though that tissue was subjected to relatively massive doses of adenosine and had some vasodilatory reserve. The local infusion of adenosine could be shown to reverse the angiotensin II–provoked uterine nonplacental vasoconstriction in that tissue served by the retrograde catheter. The cotyledonary vasculature was not responsive to adenosine and maintained an increased resistance associated with the systemic infusion of angiotensin II.

Comment

Blood flow to the female reproductive organs is responsive to the changes in hormone activity during menstrual or estrous cycling and during the unique hormone changes of pregnancy.

Both Resnik et al.[7] and Still and Greiss[8] have shown that uterine blood flow is increased by adenosine in the nonpregnant sheep. Fleet and Heap[9] have demonstrated a dose-dependent increase in uterine blood flow in response to adenosine infusion into the uterine artery via a surgically created femoral–uterine arterial shunt. In their series, nonpregnant animals responded more dramatically than did ewes on day 15 of a fertile mating. Fox and Kurpis[10] postulated the existence of a low-affinity stimulatory receptor identified in the microsomal fraction of fresh human placental homogenate and hypothesized that adenosine may stimulate blood flow locally in the placenta.

It has been stressed that adenosine is very likely a mediator of coronary blood flow and is released rapidly under hypoxic conditions with resultant dramatic increases in coronary blood flow.[11]

In our previous experiments we have demonstrated that prostacyclin, a potent uterine vasodilator in both nonpregnant and pregnant sheep, is not effective in dilating the placental vasculature. When given as an injection systemically to the near-term ewe, prostacyclin caused hypotension and vasodilation in the maternal uterus, kidneys, heart, and brain but caused vasoconstriction in the placental circulation with a 43% decrease in blood flow to the cotyledonary tissue.[3] When given as a local infusion via the uterine artery, prostacyclin caused an increase in local uterine blood flow but no change in local cotyledonary blood flow.[1] In a final series, prostacyclin was given systemically after pretreatment with systemic angiotensin II.[2] In this model, we ensured that the vasculature was constricted before prostacyclin administration. In this manner we established that prostacyclin did reverse the pharmacologic constriction of the renal and uterine vasculature but did not dilate the constricted placental vascular bed. We hypothesized that adenosine, acting via a different receptor system, might be capable of dilating a placenta previously contracted by angiotensin II.

In our experiments, the uterus responded in the predicted manner. We are confident that the local application of adenosine was effective in that there was no change in systemic blood pressure or renal resistance during the short adenosine infusion. The cotyledons that were "downstream" from the retrograde catheter should have received a concentration of adenosine similar to that traversing the adjacent myometrium. We conclude that placental vascular responses are modulated by mechanisms that are significantly different from those controlling the nonplacental uterine vascular bed. Furthermore, the prior constriction of the placenta with angiotensin II guaranteed a vasodilatory reserve in these vessels so that they could have dilated had adenosine been an effective mediator. Neither prostaglandin I_2 nor adenosine causes placental dilation in the near-term ewe although they both cause vasodilation of the adjacent uterine vasculature. Prostaglandin I_2 and adenosine should act by stimulating different sets of endothelial receptors, indicating that the placental response to vasodilators in general is anomalous.

Relationship of gonadotropin-releasing hormone, danazol, and prostaglandin blockade to ovarian enlargement and ascites formation of the ovarian hyperstimulation syndrome in the rabbit

Sheila M. Pride, B.Sc., M.D., Basil Ho Yuen, M.B., Ch.B., Young S. Moon, D.V.M., Ph.D., and Peter C. S. Leung, M.D.

Vancouver, British Columbia, Canada

The effects of pharmacologic doses of gonadotropin-releasing hormone, danazol, and indomethacin on the clinical and endocrinologic features of the ovarian hyperstimulation syndrome were studied in the rabbit. The ovarian hyperstimulation syndrome was induced with Pergonal (75 IU of follicle-stimulating hormone and 75 IU of luteinizing hormone) and a follicle-stimulating hormone–dominant gonadotropin preparation (85 IU of follicle-stimulating hormone and 53 IU of luteinizing hormone). None of the three agents tested were effective in suppressing the ovarian enlargement and ascites formation in these animals. Ascites developed despite quite significant variations in plasma and intraovarian sex steroid hormone and intraovarian prostaglandin F levels induced by danazol and indomethacin. Ascites develops in hyperstimulated women in association with both follicular and luteal hyperstimulation. In contrast, the ascites response in the hyperstimulated rabbit develops in the presence of follicular hyperstimulation alone without a significant degree of luteal hyperstimulation. (Am J Obstet Gynecol 1986;154:1155-60.)

Key words: Ovarian hyperstimulation syndrome, danazol, indomethacin, gonadotropin-releasing hormone

The ovarian hyperstimulation syndrome is a well-recognized and potentially life-threatening risk associated with ovulation induction therapy, particularly with exogenous gonadotropins.[1,2] The full-blown clinical syndrome occurs after ovulation and, if conception occurs, the process tends to be more prolonged and severe. With improved monitoring of the response to treatment, the incidence of this iatrogenic complication has been reduced but not eliminated.[1] This is, in part, a function of the narrow therapeutic index and the sometimes unpredictable patient sensitivity to such therapy. The incidence of mild, moderate, and severe ovarian hyperstimulation syndrome has been reported to vary from 8% to 23%, <1% to 7%, and <1% to 10%, respectively.[1] As ovulation induction therapy with gonadotropins becomes more widely available and the indications for its use expand (for instance, ovulation induction for in vitro fertilization), this complication may assume greater clinical importance.

The fundamental pathophysiology of ovarian hyperstimulation syndrome, particularly the third-space fluid sequestration, is not understood and specific therapeutic measures that might arrest or reverse this are not available. The purpose of this study was to determine if the pathologic manifestations of ovarian hyperstimulation syndrome could be influenced by the administration of pharmacologic doses of three compounds: gonadotropin-releasing hormone (GnRH), danazol, and indomethacin. Although each of these three agents is known to interfere with ovulation and/or ovarian steroidogenesis, these effects do not always

apply to the normal unstimulated rabbit ovary.[3-10] Pharmacologic doses of both GnRH and its agonist analogues have well-documented effects on ovarian steroidogenesis, which are demonstrable in both intact and hypophysectomized animals, supporting a direct gonadal action.[3-6] Danazol, an isoxazole derivative of the synthetic steroid 17α-ethinyl testosterone (ethisterone), competitively inhibits multiple enzyme systems involved in steroidogenesis in both the ovary and adrenal.[7,8] Indomethacin is a well-known and potent prostaglandin synthetase inhibitor that can prevent follicular rupture and ovum release.[9] Furthermore, in the rabbit model of ovarian hyperstimulation syndrome this compound may inhibit ascites formation.[10]

Material and methods

Fifty-nine virgin New Zealand White rabbits were used in three experiments. Each experiment had its own control group.

Experiment No. 1. Ten rabbits weighing between 2.5 and 3.1 kg were used. Both control (n = 5) and test animals (n = 5) received one ampule of Pergonal [75 IU of follicle-stimulating hormone (FSH) and 75 IU of luteinizing hormone (LH)] intramuscularly daily for 7 days. Test animals also received GnRH (Factrel), 440 μg/kg intramuscularly twice daily for 8 days.

Experiment No. 2. Fourteen animals (3.3 to 5.4 kg) were divided into three groups. One ampule of an FSH-dominant gonadotropin preparation (85 IU of FSH and 53 IU of LH) was given intramuscularly once daily for 7 days to both control (n = 5) and test animals. In addition, test animals received either danazol, 20 mg/kg subcutaneously (n = 5), or indomethacin, 30 mg/kg subcutaneously (n = 4) once daily for 8 days. Danazol was suspended in propylene glycol and indomethacin was suspended in sesame seed oil.

Experiment No. 3. Thirty-five animals (2.8 to 4.7 kg) were divided into four groups. Control (n = 10) and all test animals (n = 25) received one ampule of Pergonal intramuscularly once daily for 7 days. Five test animals received 20 mg/kg of danazol subcutaneously once daily for 8 days; 10 animals received 20 mg/kg of danazol subcutaneously twice daily for 8 days (total dosage of 40 mg/kg per day); and 10 animals received indomethacin, 30 mg/kg subcutaneously once daily for 8 days.

In all three experiments, animals were weighed on the first day and the last day (day 9). Serial blood samples from a marginal ear vein were drawn on days 1, 5, 7, and 9, just before administration of medications. Animals were killed by an overdose of pentobarbitol sodium (Euthansol) on the ninth day and necropsies were performed immediately. Ascites formation was assessed and assigned a score.[11] After excision, both ovaries were immediately washed in cold saline solution, blotted dry, weighed, then quickly placed in ice-cold absolute ethanol and homogenized. In experiment 3, representative sections of ovaries were excised, placed in formalin solution, and submitted for routine histologic evaluation in five controls, five animals receiving danazol, 40 mg/daily, and five animals receiving indomethacin.

Plasma and ovarian homogenate content of 17β-estradiol and progesterone and ovarian homogenate prostaglandin F were assayed by specific radioimmunoassays.[11]

Statistical analyses. Statistical analyses were performed by the Mann-Whitney test, linear correlation analysis, and the χ^2 test where appropriate. Data were compared between the treatment and control groups within each experiment. All data are presented as mean ± SEM.

Results

Experiment No. 1. Mean body weights for control and GnRH-treated animals were comparable and did not change during the course of the experiment. No differences were observed in mean ovarian weights, mean ascites score, serial plasma and ovarian 17β-estradiol, and progesterone and ovarian homogenate prostaglandin F (Figs. 1, 2, and 3).

Experiment No. 2. Mean body weights of control and test animals were similar and did not change during the course of the experiment. Compared with controls, danazol- and indomethacin-treated animals showed no appreciable differences in ovarian weights or in plasma and ovarian homogenate sex steroid concentrations (Figs. 1, 2, and 3). The ovarian homogenate prostaglandin F content of indomethacin-treated animals was significantly lower than in both control and danazol-treated animals (13.82 ± 4.41 versus 79.8 ± 30.58 and 71.18 ± 18 pg/mg of protein, respectively; $p < 0.05$; Fig. 3). One of five controls, four of five danazol-treated animals, and three of four indomethacin-treated animals developed ascites with scores ranging between 1 and 5, and the mean ascites scores are shown in Fig. 1.

Experiment No. 3

Controls (n = 10). Mean animal weights were comparable at the beginning and end of the experiment (3.71 ± 0.09 and 3.56 ± 0.08 kg). The mean ovarian weight was 2.78 ± 0.33 gm (Fig. 1; range 1.41 to 4.97 gm). All ovaries showed multiple cystic and hemorrhagic follicles over the external surfaces with few if any corpora lutea. Histologic assessment confirmed the presence of hemorrhagic follicles, cystic follicles, and minimal corpora lutea formation. Interstitial tissue generally exhibited little luteinization. Seven of the 10 controls developed ascites; the mean ascites score for this group was 2.4 ± 0.34 (Fig. 1). Plasma 17β-estradiol levels were 20.2 ± 4.5, 70.6 ± 13.76, 133.2 ± 13.2, and 85.7 ± 13.1 pg/ml on days 1, 5, 7, and 9, respectively (Fig. 2). Plasma progesterone levels did not exceed 5 ng/ml at any time. Ovarian homogenate 17β-estradiol and progesterone levels were 238.4 ± 43.6 pg/mg of protein and 3.6 ng/mg of protein, respectively. The homogenate content of prostaglandin F was 17.59 ± 2.17 pg/mg of protein (Fig. 3).

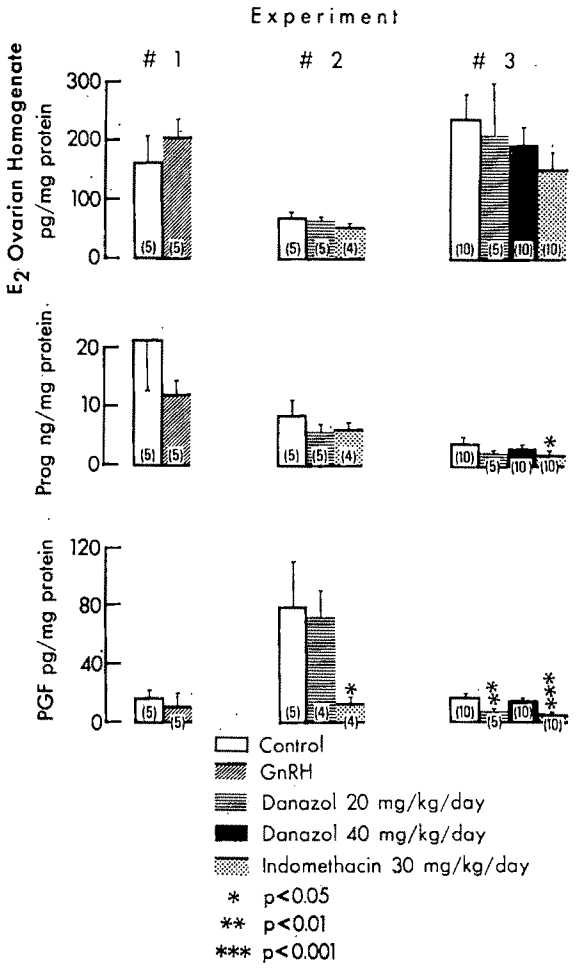

Fig. 3. Ovarian homogenate content of estradiol *(E_2)*, progesterone *(Prog)*, and prostaglandin F *(PGF)* expressed per milligram of protein in control and test animals in experiments 1, 2, and 3. Values are expressed as mean ± SEM. Comparisons and statistical analyses were drawn only between the treatment groups and controls within each experiment.

Danazol, 20 mg/kg once daily (n = 5). Mean body weights were similar to those of controls and did not

change. Ovaries were similar in gross appearance to those of controls but histologic evaluation was not obtained for this group. Ovarian weights varied widely, ranging between 2.19 and 15.2 gm; however, the mean weights were not statistically different (Fig. 1). Two of five animals developed ascites; the mean score was 1.6 ± 0.4 and was similar to that for controls (Fig. 1). Serial plasma 17β-estradiol levels exhibited marked variability but mean levels were comparable to those of controls; plasma progesterone (Fig. 2) and ovarian homogenate 17β-estradiol and progesterone levels were also similar (Fig. 3). Homogenate prostaglandin F content was significantly lower than that of controls (6.96 ± 2.3 versus 17.59 ± 2.17 pg/mg of protein; $p < 0.01$; Fig. 3).

Danazol, 20 mg/kg twice daily (n = 10). Compared with those of controls, mean body weights and ovarian weights (range 1.74 to 10.1 gm; mean 4.08 ± 0.8 gm) were similar (Fig. 1). No apparent differences in the gross and histologic appearances of the ovaries were observed. Ascites formation was evident in nine animals, and the mean ascites score was comparable to that of controls (Fig. 1). Plasma 17β-estradiol levels were significantly higher on days 5, 7, and 9 while the plasma progesterone response was minimal and did not differ from that of controls (Fig. 2). Ovarian homogenate contents of 17β-estradiol, progesterone, and prostaglandin F were similar (Fig. 3).

Indomethacin, 30 mg/kg once daily (n = 10). These animals had significantly lower body weights on day 9 of the experiment (3.18 ± 0.13 versus 3.56 ± 0.08 kg; $p < 0.01$), while body weights at the start were comparable (Fig. 1). There were no apparent differences in the general health of the animals. External ovarian appearances were similar to those of controls, as were the histologic sections, which showed the presence of hemorrhagic follicles, cystic follicles, and few if any corpora lutea. There was no evidence of ovulation. Mean ovarian weights were similar (Fig. 1). Seven of the 10 animals developed ascites with a mean score of 1.9 ± 0.23 (Fig. 1). Plasma 17β-estradiol levels on days 7 and 9 were significantly depressed, while the plasma progesterone response was minimal (Fig. 2). Ovarian homogenate prostaglandin F was significantly depressed (5.27 ± 1.18 versus 17.59 ± 2.17 pg/mg of protein, $p < 0.01$; Fig. 3).

Comment

In humans, the ovarian hyperstimulation syndrome is a complex series of events comprising marked ovarian enlargement due to multiple follicular and hemorrhagic cysts, multiple corpora lutea, and stromal edema; ovarian vascularity is also increased. In addition enhanced vascular permeability results in acute third-space fluid shifting with its attendant sequelae of hypovolemia, oliguria, renal failure, electrolyte disturbances, hyperviscosity, and hypercoagulability.[1] The third-space fluid shifting and its consequences contribute most significantly to the morbidity and mortality associated with this complication. In these experiments with the rabbit model,[2] there appeared to be wide individual variations in animal responses to a given dosage of Pergonal. Clinically, this is also commonly observed.[1]

We also found that the rabbit can develop an ascites response to gonadotropin hyperstimulation of the ovarian follicles with a minimal to essentially normal luteal response. The observations in the current studies indicate that the ascites response of the hyperstimulated female rabbit shares similarities (ovarian enlargement, multiple hemorrhagic follicles, hyperestrogenemia) and differences (lack of luteal hyperstimulation), as compared with the syndrome in humans.

Hyperstimulation of the ovaries was observed in all three experimental groups as reflected by ovarian enlargement and plasma 17β-estradiol values. In these experiments, mean ovarian weights were approximately tenfold to thirtyfold heavier than those in placebo-treated control animals of comparable body weight. In comparison, rabbits (body weight 2.1 ± 0.1 kg) were given intramuscular injections of saline solution in lieu of gonadotropins as described in the present experiments (placebo controls), the mean ovarian weight was 0.2 ± 0.03 gm (unpublished data).

Mean plasma 17β-estradiol levels observed in the three experiments reported here exceeded values observed in rabbit pseudopregnancy, albeit levels were generally lower in experiment 2, where an FSH-dominant gonadotropin preparation had been used (Fig. 2). No correlation between plasma 17β-estradiol and ascites formation was observed. When we induced pseudopregnancy in 10 rabbits with 100 IU of human chorionic gonadotropin intravenously, peripheral plasma 17β-estradiol levels on days 5, 7, and 9 of pseudopregnancy did not exceed 13 pg/ml and the range of progesterone for comparable phases of pseudopregnancy was 13.31 ± 2.35 to 25.5 ± 4.4 ng/ml (unpublished data). Although plasma progesterone levels in experiment 1 fell within the pseudopregnancy range (Fig. 2), levels in experiments 2 and 3 were much lower, compatible with minimal corpus luteal function. Nevertheless, ascites formation occurred in all three experimental groups. The reason for the higher plasma progesterone response in control animals of experiment 1, compared with those in experiment 3, where both groups received the same amount of exogenous gonadotropin stimulation, is unclear. It may be that experiment 1 controls, having significantly lower mean

body weights (2.67 ± 0.06 versus 3.7 ± 0.10 kg; $p < 0.05$), received relatively larger amounts of Pergonal per kilogram of body weight.

Within each of the experiments, ascites formation had no consistent relationship to ovarian weight. The degree of ascites formation was similar in the less hyperstimulated animals of experiment 2 as compared with that observed in the other two experimental groups. In a review of patients with ovarian hyperstimulation, all of whom had severe ovarian enlargement (ovaries >12 cm), only 36% developed clinically apparent ascites.[1] In yet another report, third-space fluid sequestration in the form of hydrothorax occurred without any significant ovarian enlargement.[2]

Pharmacologic doses of both native GnRH and its agonist analogues have been shown to inhibit steroidogenesis via a direct gonadal action, mediated by specific high-affinity GnRH receptors in rats and guinea pigs.[3, 4] There are data to suggest that rabbit ovaries also contain GnRH or GnRH-like receptors.[5] The dosage of GnRH per kilogram of body weight used in experiment 1 was thirteenfold greater than that used to induce luteolysis of existing corpora lutea in pregnant rabbits and comparable to that previously shown to inhibit ovulation and steroidogenesis in rats.[4, 6] From our data, these very high doses of GnRH did not suppress steroidogenesis in the hyperstimulated rabbit, nor did they influence the other features associated with the ovarian hyperstimulation syndrome. Since natural GnRH has a relatively short half-life, the use of more potent and longer-acting GnRH agonist analogues offers an alternate approach that may yield different results.

Danazol is known to inhibit steroidogenic enzymes in the ovary and adrenal. It blocks aromatization of androgen to estrogen and interferes with progesterone production and luteal function.[7, 8] The doses of danazol we used were at least fourfold the dose that suppressed gonadal steroid production in rats.[7] However, in experiments 2 and 3, danazol, 20 mg/kg once daily or 20 mg/kg twice daily, did not depress steroidogenesis. Indeed, at the higher dose schedule in experiment 3, plasma 17β-estradiol was significantly elevated on days 5, 7, and 9. In patients receiving large doses of danazol, serum 17β-estradiol levels were also elevated.[14] Since danazol competes with 17β-estradiol for estradiol receptors,[13] it is conceivable that increased circulating 17β-estradiol may result from decreased tissue binding. In experiment 3, animals receiving 20 mg/kg of danazol once daily had significantly lower ovarian prostaglandin F as compared with that of controls. However, ovarian prostaglandin F was similar to that of controls in animals receiving a higher dose of danazol (20 mg/kg twice daily). The less hyperstimulated animals in experiment 2 that were given 20 mg/kg/day also did not show significant depression of ovarian prostaglandin F; the reason for the depression of ovarian prostaglandin F observed in experiment 3 is unclear. Despite these endocrine changes seen with the use of danazol, the clinical manifestations of ovarian hyperstimulation syndrome (ascites formation and ovarian enlargement) were unaffected.

It has been suggested that prostaglandins are important mediators of the altered vascular permeability associated with the ovarian hyperstimulation syndrome since inhibition of prostaglandin synthetase by indomethacin suppressed ascites formation in the hyperstimulated rabbit.[1, 10] Our results do not support this contention. With the use of an identical dosage schedule for administering indomethacin (experiments 2 and 3), we were able to demonstrate significant suppression of ovarian prostaglandin F (presumably with other prostaglandins being inhibited as well). Despite this, ascites formation was uninfluenced, suggesting that prostaglandins are not obligatory mediators of the third-space fluid shifting. Indomethacin had no effect on ovarian weight in either experiment. Although steroidogenesis was not significantly affected in experiment 2, indomethacin in the more stimulated animals of experiment 3 significantly lowered plasma 17β-estradiol levels on days 7 and 9. Indomethacin significantly suppressed ovarian progesterone but not 17β-estradiol content. High concentrations of indomethacin can exert pharmacologic effects that are independent of prostaglandin inhibition. These effects include inhibition of cyclic adenosine monophosphate–dependent protein kinase, and indomethacin could interfere with steroid hormone production via this mechanism.[15] Nevertheless, despite its effects on ovarian steroidogenesis and good suppression of ovarian prostaglandin, indomethacin in pharmacologic doses did not influence the clinical features of the ovarian hyperstimulation syndrome (increase in ovarian weight and ascites formation).

In summary, GnRH, danazol, and indomethacin as used in these experiments were not effective in suppressing ovarian hyperstimulation and/or ascites formation. The gonadotropin-induced ascites response in the rabbit occurred despite quite marked variation in the clinical and hormonal response of the ovaries. In contrast to the syndrome in humans, where the ascites response is seen in the presence of follicular and luteal hyperstimulation, the development of ascites in the hyperstimulated rabbit was observed in the absence of significant luteal hyperstimulation.

We are grateful to the Serono Company, Randolph, Massachusetts, for the generous gift of the FSH-dominant gonadotropin preparation and part of the Per-

gonal used in this study. We also wish to thank Mr. Antoni Duleba for his interest and aid in this project.

The effect of a calcium channel blocker (nifedipine) on uterine blood flow in the pregnant goat

Jean Claude Veille, M.D., John M. Bissonnette, M.D., and A. Roger Hohimer, Ph.D.
Portland, Oregon

The purpose of this study was to analyze the changes in maternal uterine blood flow, maternal arterial blood pressure, and maternal heart rate with the intravenous administration of nifedipine in pregnant, unanesthetized pygmy goats. Bolus injections of 2.5 to 45 μg/kg of maternal weight were used. Uterine blood flow did not fall significantly. A transient fall in maternal arterial blood pressure occurred in the first minute after the injection, but the pressure returned to normal after 5 minutes. Maternal heart rate increased immediately after the bolus of nifedipine and returned toward the control value by 30 minutes. (AM J OBSTET GYNECOL 1986;154:1160-3.)

Key words: Uterine blood flow, pregnant pygmy goat, calcium channel blocker

Nifedipine, a calcium channel blocker, prevents the entry of ionized calcium in the slow channels of the cell membrane and results in an inhibition of smooth muscle contraction.[1,2] Its use in cardiology has been mostly in the treatment of angina pectoris, causing vasodilation of the coronary vascular bed, and in hypertension, causing an inhibition of vascular smooth muscle tone.[3] Since there is a need for a potent tocolytic agent with minimal side effects, some investigators have examined the effects of this drug on uterine contractions. In vitro studies done on uterine strips showed that nifedipine inhibited oxytocin-induced contractions.[4,5] Administration of nifedipine to women with dysmenorrhea,[6] to women undergoing midtrimester abortion induced by prostaglandin $F_{2\alpha}$,[7] and to women with postpartum uterine contractions[8] resulted in successful inhibition of uterine activity. Because of these observations nifedipine was used successfully in the treatment of 10 patients in premature labor.[9] However, since both uterine and vascular smooth muscle are affected by nifedipine, hemodynamic side effects are of concern. When a bolus

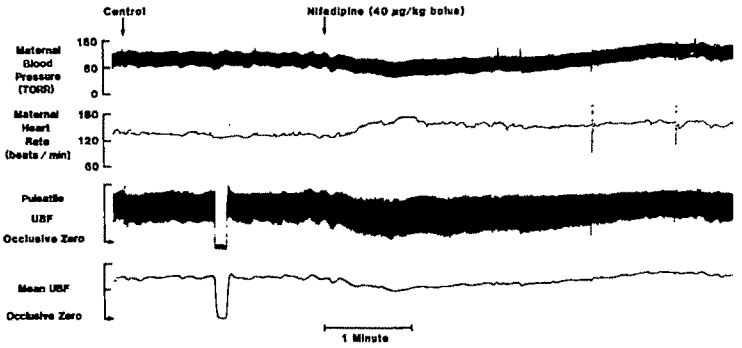

Fig. 1. Strip chart recording of maternal arterial pressure, maternal heart rate, and uterine blood flow *(UBF)*. A control period is indicated, during which an occlusive zero was obtained. An intravenous bolus of 40 µg/kg was given during 1 minute, as indicated. A fall in maternal arterial pressure and in uterine blood flow was observed. Maternal heart rate increased immediately after the bolus injection.

of nifedipine was given to nonpregnant unanesthetized dogs, a 30% fall in mean arterial pressure was seen.[10] Infusion of nifedipine at 10 µg/kg/min in pregnant ewes resulted in a significant fall in maternal blood pressure and systemic vascular resistance (see reference 14). Such a fall in pressure in a pregnant animal might significantly affect maternal uterine blood flow,[11] reduce placental perfusion, and thus result in a deleterious effect on the fetus. The purpose of this study was to analyze the changes in uterine blood flow and in maternal blood pressure and heart rate during intravenous bolus administration of nifedipine in the pregnant pygmy goat.

Material and methods

Six time-bred pregnant pygmy goats weighing between 15 and 40 kg, with a mean gestational age of 126 ± 2 days (term = 150 days), were used in this study. Each was fasted overnight and given atropine. Anesthesia was induced with intravenous barbiturate. After intubation, the goats were ventilated with halothane (1% to 2%) and a balance of 50% oxygen and 50% nitrous oxide. A low midline incision was made and the pregnant horn was located. The uterine artery supplying that horn was cleared of connective tissue to allow placement of an electromagnetic flow probe transducer with a lumen diameter between 4 and 6 mm (Carolina Medical Electronics). An inflatable occluder, made of silicone rubber, was placed 1.0 to 1.5 cm distal to the flow probe. The carotid artery and the jugular vein of the goat were isolated and cannulated nonoccclusively with polyvinyl catheters. All catheters and wires were routed subcutaneously to the maternal flank and kept in a cloth pouch sewn to the skin.

At least 3 days passed before the animals were studied. Nifedipine (supplied by Dr. N. Gerber, Pfizer, Ltd.), in a powder form, was prepared on the morning of the experiment in a light-protected environment. Nifedipine, 5 or 10 mg, was dissolved in 20 ml of 95% ethyl alcohol and 30 ml of distilled water, yielding a 100 µg/ml or a 200 µg/ml solution, respectively. The flow probe wires were connected to the flowmeter (Model 501, Carolina Medical Electronics), which was then balanced and nulled. Both pulsatile and mean (0.3 Hz low-pass filter) uterine blood flow were recorded on a strip-chart recorder (Model R611, Beckman Instruments). The maternal arterial catheter was connected to a pressure transducer (Statham Model 23Db), which was positioned at the midthoracic level of the goat. Maternal heart rate was determined by a cardiotachometer (Beckman Model 9857) triggered by either the arterial pressure pulse or the flow.

When the instrumentation was operational, the occluder was inflated for a 10-second period. This occlusive zero was used for the no-flow reading and was obtained after each study. Only trials in which the occlusively determined zero flow outputs did not differ by more than 5% with reference to the output determined during an initial 30- to 40-minute control period were accepted for analysis. After the control period, a bolus of nifedipine was infused into the maternal jugular vein. The initial dose was either 2.5 or 5 µg/kg and this was followed by increased doses of the drug. We allowed 40 to 60 minutes to elapse between each bolus of nifedipine and performed three to five studies per day in each animal. In all, 102 studies were performed in the six animals.

Uterine blood flow, mean arterial blood pressure (systolic pressure + 2 diastolic pressure/3)[12] and maternal heart rates were transcribed from the chart records at 10-second intervals for the first 5 minutes after the injection of nifedipine. These were averaged for the first minute (immediate response) and separately for the second to the fifth minute (early response). The data were transcribed at 30-second intervals from the fifth to thirtieth minute and averaged (late response).

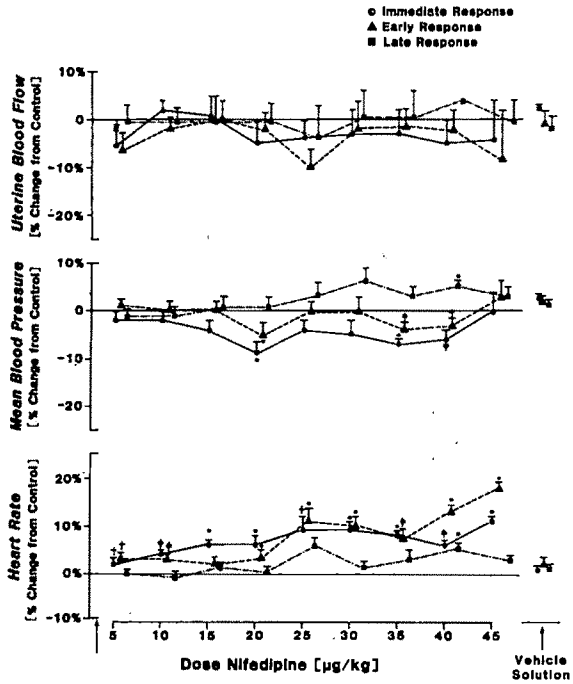

Fig. 2. Uterine blood flow, maternal arterial pressure, and maternal heart rate as a function of the bolus dose of nifedipine at three periods after the drug: immediate (0 to 1 minute), early (1 to 5 minutes), and late (5 to 30 minutes). Each point represents the average of seven to nine studies. (* = $p < 0.01$; † = $p < 0.05$; ‡ = $p < 0.02$.)

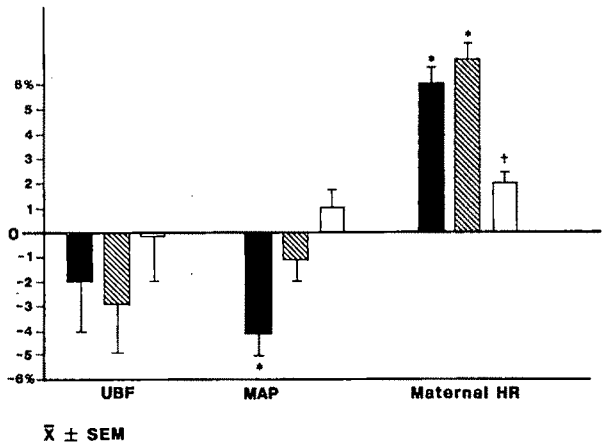

Fig. 3. Data obtained by pooling all doses of nifedipine in Fig. 2 showing percent of change from control for uterine blood flow *(UBF)*, maternal arterial pressure *(MAP)*, and maternal heart rate *(HR)*. *Solid bars* = Immediate response (0 to 1 minute); *hatched bars* = early response (1 to 5 minutes); *open bars* = late response (5 to 30 minutes). (* = $p < 0.01$; † = $p < 0.05$.)

Uterine blood flow is expressed as a percentage of the control blood flow and not in terms of absolute blood flow, as only a portion of the total uterine blood flow was measured and because of the inherent difficulty in calibrating chronic flow probes.[13] Mean arterial pressure and heart rate are also expressed as a percentage of the control value obtained for each study day. Data for each dose of nifedipine were averaged and compared with control values by a paired *t* test with a two-tailed table of significance.

Results

During the control period mean arterial pressure in these goats averaged 85 ± 1 torr (±SEM) and heart rate was 131 ± 1 bpm. By definition, the control uterine blood flow was 100%. Fig. 1 shows the response of maternal blood pressure, heart rate, and uterine blood flow to a bolus of 40 µg/kg of nifedipine. The fall in blood pressure and uterine blood flow accompanied by a rise in heart rate observed in the immediate and early periods after the bolus was not typically as pronounced as seen in this study even at the higher doses of nifedipine.

In Fig. 2, the average changes in uterine blood flow and in maternal arterial pressure and heart rate observed for boluses of nifedipine over a range of 5 to 45 µg/kg are depicted. There was no significant change in uterine blood flow at either the immediate (1 minute), the early (2 to 5 minutes), or the late (5 to 30 minutes) period after the drug. Maternal arterial pressure fell by 6% to 10% at nifedipine doses of 20, 35, and 40 µg/kg. This significant decline was seen during the immediate and early time periods and did not persist beyond 5 minutes. Maternal heart rate increased significantly during the 5 minutes after the bolus and the increase was more pronounced at a dose of ≥25 µg/kg. Heart rate returned toward control values in the next 25 minutes. Fig. 2 shows the infusion of the vehicle used in these studies had no effect on uterine blood flow, arterial pressure, or heart rate.

In Fig. 3, we have grouped the results at all doses of nifedipine. The fall in mean arterial pressure was confined to the first minute after the nifedipine bolus and the maternal tachycardia was seen to persist for 30 minutes although the change seen in the late period was minor.

Comment

A bolus infusion of nifedipine (20 µg/kg) in unanesthetized dogs produced a 30% fall in mean arterial pressure.[10] If a similar fall in blood pressure were to occur in a pregnant animal and the uterine circulation did not dilate, a corresponding fall in uterine blood flow would be anticipated.[11] With the use of bolus infusions up to twice that which caused hypotension in the dog, we have observed only a minor fall in blood pressure in pregnant pygmy goats. In this respect, our results are consistent with those recently reported by Golichowski et al.[14] in pregnant sheep. The study de-

sign differed from ours in that Golichowski et al. used 30-minute constant infusions of nifedipine over the range 1 to 10 μg/kg/min. They observed a 12% fall in blood pressure at the highest dose.

Although a transient fall in uterine blood flow was seen in some studies (Fig. 2), when flow was averaged, there was no significant fall to this organ. This indicates that the tissues supplied by the vasculature distal to our flow probe dilated at least to the extent that perfusion pressure fell. Blood flow measured by a probe on the uterine artery goes to two vascular beds, the placenta and the myoendometrium, which may show different responses. In the past we have shown that the fall in uterine blood flow that occurs during exercise in the pregnant pygmy goat[12] is seen primarily in the myoendometrial bed. In these studies we used microspheres to separate blood flow in the uterus into its two components and found that placental or cotyledonary flow fell <10% while that to the myoendometrium declined to less than half of the resting level. It should be noted that the response in both these vascular beds was in the same direction. It is possible, in the present experiments with nifedipine, that a fall in placental blood flow was balanced by an increase in flow to the myoendometrium, such that no change was seen in total uterine blood flow. However, on the basis of the previous studies cited above, in which both placental and nonplacental vasculatures showed a qualitatively similar response to a given perturbation, we feel that it is unlikely that the uterine circulation underwent a combined constriction and dilation in its two vasculatures after the bolus injection of nifedipine.

In conclusion we have shown that the uterine circulation of the pregnant pygmy goat does not experience any change in flow rate after bolus injections of the calcium channel blocker nifedipine up to 45 μg/kg.

CORRESPONDENCE

Goiter in pregnancy

To the Editors:

The article by Long et al. (Long TJ, Felice ME, Hollingsworth DR. Goiter in pregnant teenagers. AM J OBSTET GYNECOL 1985;152:670) addresses the question of a possible goitrogenic effect of pregnancy. Clearly, many of the discrepancies between studies can be explained by geographic, racial, and environmental differences in the study populations. Thus urinary iodine excretion differs widely from country to country and also within countries.

We, however, wish to draw attention to the inexactness and irreproducibility of the clinical evaluation (palpation) of thyroid size[1] and stress that such an evaluation does not with any reliability allow a quantitative evaluation of thyroid size. Such an evaluation could have been achieved by use of ultrasound[2] and is necessary if one wishes to demonstrate alterations in thyroid size in a range of thyroid volume where no goiter is evident. Therefore, an increase in thyroid volume could well have been demonstrated in spite of the failure to demonstrate a difference in goiter frequency between pregnant and nonpregnant subjects.

Recently a number of factors have been found to influence thyroid size. Thus sex, age, and body weight[2] as well as the presence of liver[3] and kidney disease[4] and possibly excessive alcohol intake[3] influence thyroid volume determination. Cigarette smoking is associated with a marked increase in goiter frequency[5] and the menstrual cycle in healthy women is associated with cyclic alterations of thyroid volume of more than 50% (unpublished data). If a valid comparison is to be made between pregnant and nonpregnant subjects it is mandatory that the two groups are comparable with respect to these variables.

From the data presented by Long et al., in our opinion the question whether thyroid size is increased during pregnancy has not been answered. A longitudinal study of ultrasonically measured thyroid volume in pregnant women might possibly give this answer.

Reply

To the Editors:

We would like to express our appreciation to Drs. Hegedüs, Rasmussen, and Karstrup for their interest in our study on the occurrence of goiter in pregnant and nonpregnant female adolescents. We feel they have understood the purpose and scope of our investigation.

We feel that the likelihood of iodine deficiency in our region is unlikely and believe that it would not have been experimentally useful or clinically practical to measure urinary iodine excretion in our patient population.

It is our opinion that although ultrasound assessment of the thyroid glands (to confirm enlargement) in our goitrous adolescent population would have been scientifically elegant, it would not have been cost-effective for our patient population and thus was not clinically justified.

Instead, we elected to be less exact and to adopt the current internationally accepted World Health Organization standards for the determination of thyroid size by palpation.

We feel that our observations have scientific merit and are of clinical usefulness for practicing physicians.

Thank you for your interest! We look forward to further entries in the medical literature regarding the validity of goiter diagnosis by palpation, and it would certainly be of interest to thyroidologists and obstetricians in our country if such an extensive ultrasound study could be performed on pregnant teens in Denmark.

Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein

To the Editors:

Recently, Sawada et al.[1] reported on determination of serum immunosuppressive acidic protein in patients with ovarian cancer. The authors concluded that measurements of this protein are a valuable adjunct to the conventional diagnostic methods and a useful procedure for the monitoring of the results of treatment.

Furthermore, the authors pointed out that immunosuppressive acidic protein differs from α_1-acid glycoprotein. This may apply to physicochemical characteristics such as isoelectric point, molecular weight, and carbohydrate content,[2] but according to Tamura et al.[2] the behavior of immunosuppressive acidic protein in immunodiffusion and immunoelectrophoresis is identical to that of normal human α_1-acid glycoprotein.

Sawada et al. used radial immunodiffusion for the measurement of immunosuppressive acidic protein without discussing whether they quantitated immunosuppressive acidic protein, α_1-acid glycoprotein, or a mixture of the two glycoproteins. In order to elucidate this problem we have investigated 33 serum samples from 15 patients who had or were thought to have cancer of the ovary.

Each of the samples was tested by radial immunodiffusion in two agar plates; one contained anti–immunosuppressive acidic protein (commercially available from Sanko Junyaku Co. Ltd., T.M.M. Bldg., 1-10-6 Iwamoto-Cho, Chiyoda-Ku, Tokyo 101, Japan) and the other anti–α_1-acid glycoprotein (commercially available from Hoechst, Verkauf Pharma, Diagnostika, D-6230 Frankfurt [Main] 80, West Germany). All the samples formed ring precipitates in both plates. The diameter of the precipitates was measured and calculated as micrograms per milliliter by means of standard curves. The content of immunosuppressive acidic protein and α_1-acid glycoprotein in each sample was marked by one single point in a coordinate system having the immunosuppressive acidic protein and α_1-acid glycoprotein values as ordinate and abscissa axis, respectively. The results of the two methods are shown in Fig. 1. The values appear highly correlated ($r = 0.994$). A linear regression analysis by means of the method of least squares gave the following equation: $y = 0.612x - 28.795$. The standard deviation of the slope was 0.010. Measurements of standards with known content of marker by both methods gave values in agreement with the equation.

In conclusion, single radial immunodiffusion performed in the commercially available plates used by us did not allow us to distinguish between immunosuppressive acidic protein and α_1-acid glycoprotein. This finding is in agreement with that of Tamura et al.,[2] who concluded that the behavior of immunosuppressive acidic protein in immunodiffusion is indistinguishable from that of normal human α_1-acid glycoprotein.

Therefore, which of the two plates should be preferred for marker determination in ovarian cancer depends on criteria other than the ability to distinguish between immunosuppressive acidic protein and α_1-acid glycoprotein. However, the importance of immunosuppressive acidic protein in the clinical assessment of

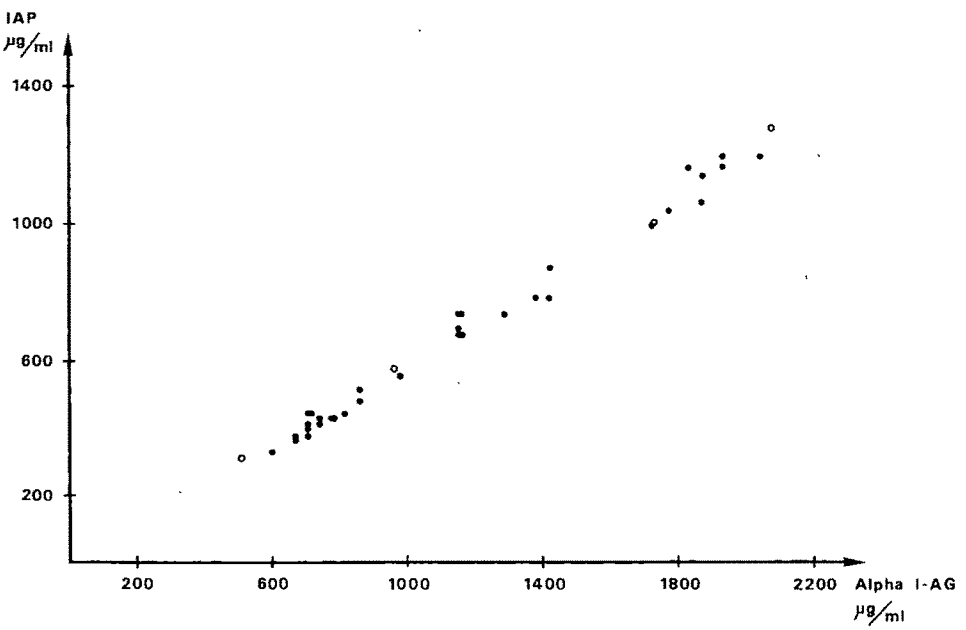

Fig. 1. Corresponding values of immunosuppressive acidic protein and α_1-acid glycoprotein measurements performed on the same serum sample. *Open circles* = four standards; each point represents the mean value of five replicates on each type of plate. *Solid circles* = 33 serum samples. *IAP* = Immunosuppressive acidic protein; *Alpha 1-AG* = α_1-acid glycoprotein.

patients with ovarian cancer seems to be a problem that needs further investigation.

Measurements of delta optical density at 450 nm in SS disease

To the Editors:

I read with interest the recent article by Lindsay and Lupo concerning false elevations of amniotic fluid delta optical density at 450 nm in patients with SS disease and hyperbilirubinemia (AM J OBSTET GYNECOL 1985; 153:75). I first reported this observation in a sickle cell patient in 1978 (AM J OBSTET GYNECOL 1978;130:103). In addition, two additional cases have recently been reported from our laboratory.[1]

I think these collective cases should serve as adequate warning to obstetricians who are managing patients with potential maternal-fetal blood group incompatibilities and who coincidentally have maternal hyperbilirubinemia. The need for intrauterine transfusion and/or early delivery should be very cautiously deliberated.

I would like to make one last comment about the paper of Lindsay and Lupo. In their last paragraph they state that this false elevation of bilirubin level in the amniotic fluid documents indirectly the passage of bilirubin from the maternal to the fetal compartment. I do not think this is necessarily the case. The normal transport of bilirubin is from the fetal to the maternal compartment. An elevation in the fetal compartment as a result of a maternal elevation probably reflects a buildup in the fetal compartment because of inhibition of flow from the fetal to the maternal compartment rather than a flow from mother to fetus. Except in extreme cases of acute maternal hyperbilirubinemia, I doubt that the net flow is ever from the maternal to the fetal compartment.

Reply

To the Editors:

I would like to thank Dr. Nelson for his interest in our report. He presents a plausible mechanism for the elevation of bilirubin in the amniotic fluid, which unfortunately cannot be substantiated by experimental data. Lipsitz et al.[1] presents data which may indirectly support the passage of bilirubin from the maternal to fetal compartment.

In their report they noted that the level of cord blood and maternal serum unconjugated bilirubin was similar. If amniotic fluid elevation was from inhibition of transport, one would expect the level of unconjugated bilirubin in the cord blood to be higher than that in the maternal serum. In the Lipsitz report this was not the case, as the cord blood bilirubin was 9.8 mg/ml and that in maternal serum at the time of delivery was 11 mg/ml. Unfortunately in our report we did not have access to cord blood bilirubin levels. Certainly, further study is warranted.

Breast-feeding in thrombocytopenic neonates secondary to maternal autoimmune thrombocytopenic purpura

To the Editors:

We would like to comment on the statement of Martin et al. (Martin JN, Morrison JC, Files YC. Autoimmune thrombocytopenic purpura: Current concepts and recommended practices. AM J OSTET GYNECOL

1984;150:86.) discouraging breast-feeding in thrombocytopenic infants born to women with autoimmune thrombocytopenic purpura.

A recent patient of ours with autoimmune thrombocytopenic purpura and previous splenectomy was referred to our center for management of the disease during her third pregnancy. She had a first child by vaginal delivery with neonatal thrombocytopenia and cerebral hemorrhage with persistent neurologic deficit, and a second child died after vaginal delivery with intracranial hemorrhage. She received steroids in the last 3 months of her pregnancy because of severe thrombocytopenia (<10,000/mm^3) and started labor at 34 weeks. The premature baby was delivered by cesarean section and showed disseminated bruises. The baby's platelet count was <10,000/mm.^{3} Platelet transfusion was given and exsanguination transfusion was performed, corticosteroid therapy was started, 1 mg/kg/day, and platelet transfusions were continued for 2 weeks. The clinical status deteriorated because of sepsis and respiratory distress. Antibiotics and oxygen were administered, and the clinical situation improved. The baby was first fed by nasogastric tube with the mother's milk when he was 5 days old; when he was able to suck, breast-feeding was started without deterioration of his platelet count. Corticosteroids were stopped after 2 weeks and breast-feeding was continued; the platelet count remained at 145,000/mm^3 and no more platelet transfusions were required.

Although it is only one case, we have evidence that in this severely thrombocytopenic baby, breast-feeding did not accentuate the thrombocytopenia. In a letter of Kelemen et al.[1] there is only a suggestion that platelet counts in the babies reported by Jones et al.[2] were lowest between the second day and fourth day as a result of breast-feeding, but there is no proof that this was the cause. In fact, no absorption of breast milk antibodies could be demonstrated in humans,[3] so we think that more cases are needed to establish whether breast-feeding is safe or not in these cases.

To the Editors

We would like to thank Drs. Meschengieser and Lazzari for communicating their recent experience with a parturient who had autoimmune thrombocytopenic purpura after splenectomy and who, after cesarean birth of her thrombocytopenic preterm infant, contributed breast milk and later breast-fed without apparent adverse effect on the neonatal platelet count.

Their case report serves to reinforce the likelihood of severe fetal thrombocytopenia in the splenectomized parturient with autoimmune thrombocytopenic purpura. Their finding that breast-feeding beginning on the fifth day did not worsen the neonatal thrombocytopenia is valuable information. We agree that further study and discussion is needed to clarify this issue and suspect that the benefits of breast-feeding in the preterm infant especially may outweigh theoretical or actual risk.

Mobiluncus-specific antibodies in a postoperative infection

To the Editors:

Mobiluncus, a bacterium closely related to bacterial vaginosis, has during the last year been reported by two different authors to give deep infections.[1, 2] Serologic studies have, however, not yet been able to demonstrate antibodies against *Mobiluncus* in patients with bacterial vaginosis.[3] In this letter we present the result of the case of an abdominally hysterectomized woman with postoperative infection of *Mobiluncus,* in which we have used an indirect immunofluorescence assay to measure *Mobiluncus*-specific antibodies in serum.

Whole untreated bacterial cells were used as antigen, and screening for the isolate with highest antigenic activity was performed by enzyme-linked immunosorbent assay. The chosen isolate, *KB,* gave a reaction two twofold dilutions higher than the type strain of *Mobiluncus curtisii* and five twofold dilutions higher than the isolate with the poorest reaction. In indirect immunofluorescence assay approximately 10^5 bacteria per milliliter from 3-day-old cultures suspended in 0.01mol/L of phosphate-buffered saline solution were placed on microscopic slides, dried in air, and used without fixation. To each well on the microscopic slide 20 μl of serum diluted 10-fold and further diluted twofold (10, 20, 40, etc.) was applied. After incubation in a moist chamber for 20 minutes at 37° C, the slides were washed in phosphate-buffered saline solution and the slides were stained with fluorescein isothiocyanate–labeled sheep antihuman immunoglobulin (National Bacteriological

Laboratory, Stockholm, Sweden). As controls slides with only conjugates and with serum diluted in a 1 : 10 ratio and the conjugate eliminated were used. After incubation for 20 minutes in a moist chamber at 37° C the slides were washed in phosphate-buffered saline solution 10 minutes and observed for fluorescence in a Zeiss fluorescence microscope with use of Ploem optics and filters. The reactions were conventionally graded: −, 1+, 2+, 3+, and 4+. Reactions graded 2+ to 4+ were recorded as positive.

The patient, a 43-year-old woman, para 2, in 1980 had a cervical dysplasia and in 1981 underwent a minilaparotomy for the purpose of sterilization. In March 1985 an abdominal hysterectomy was performed because of menorrhagia. The histopathologic examination showed leiomyoma of the uterus and an unspecific cervicitis. On the fourth postoperative day the patient became febrile and had low pelvic pain. Examination revealed a foul-smelling, bloodstained discharge and a small palpable induration in the top of vagina. *Mobiluncus* species and gram-positive anaerobic cocci were isolated from the top of vagina. The patient was treated with metronidazol, 500 mg three times daily, and amoxicillin, 700 mg three times daily, for 7 days. She became afebrile and clinically well and was discharged from the hospital. Four weeks later she returned to the hospital with subfebrility and foul-smelling discharge for the previous week. Presence of *Mobiluncus* was demonstrated by a wet-smear study, and gynecologic examination was normal except for a small mass in the top of vagina, which was demonstrated by ultrasound as a cystic cavity, 2 cm in diameter. She received additional treatment with metronidazol, 500 mg three times daily, but this time for 10 days, since we have seen therapy failure with the shorter duration of treatment.[4] The patient recovered from the symptoms and wet-smear and gynecologic examinations after 1 and 5 months revealed no signs of *Mobiluncus* infection. Blood samples were collected for analysis of antibodies against *Mobiluncus*.

The first serum, from 56 days after the operation, gave a titer of 1:320 when tested for IgG antibodies; the second taken 64 days later gave a titer of 1:640. Serum taken 62 additional days later showed reduction in titer to 1:320, and the last serum after an additional 30 days gave a titer of 1:80. The reduction, in titers here is significant, since they are much higher than controls or what other authors found in serologic studies of patients with bacterial vaginosis.[5] A remarkable finding is the specificity of the antibodies, showing reactivity with *Mobiluncus curtisii* but not with *Mobiluncus mulieris* and, in addition, a possible means to discriminate between different isolates among *Mobiluncus curtisii*, a sensitivity which is higher than serum from immunized rabbits.[5] The sera did not react with a wide panel of unrelated bacteria.

These findings indicate the need for further clinical and laboratory investigation in order to clarify whether infections of *Mobiluncus* have to be taken into consideration as an etiologic agent of infections of the female genital tract other than bacterial vaginosis.

Finger extension of transverse uterine incision

To the Editors:

I agree with the article by Dr. Jovanovic (Incisions of the pregnant uterus and delivery of low-birth weight infants. Am J Obstet Gynecol 1985;971:971-4) except his last sentence, "Thus the fingers should never be used to tear the pregnant uterus transversely . . .."

The rationale for the finger technique was (1) that it enabled one to separate the transverse fibers of the lower uterine segment without cutting the fibers and (2) that it is technically easier to separate the fibers with the fingers than by cutting.

When the fibers are cut, bleeding is increased and the procedure toward the operator must be done backwards with the Bendage scissors—or else the assistant must assist in that portion of the operation; if the assistant is not trained, then the operator must do it himself.

The finger technique is more efficient also because the fingers extend the incision to the limits of the presenting part and not beyond. This affords the minimal length of the incision necessary.

The paper is provocative and timely. It also includes the method for delivering the small fetus. Vaginal delivery is still the best method.

Corona, California 91719

Reply

To the Editors:

I would like to thank Dr. Gerace for his interest and support of my concept as presented in the article.

In the paper I explained why the so-called "finger technique" created the smallest incision on the uterus and pointed to serious consequences of this small opening on the uterus. These serious complications are injuries of parametrial vessels, involuntary extension of the incision, and midline uterine incision. Bleeding from the cut or finger tear of the low uterine segment is irrelevant as a serious complication.

In addition to what I already said in the paper, I would like to add one point. If we have a hollow, elastic body, a shape such as the uterus, and we make a small transverse incision with a knife and try to extend this incision to the side, we will see that this is impossible because of the elasticity. As an end result there will be a small tear, which is the main point of my paper.

Lupus anticoagulant and pregnancy

To the Editors:

A large number of publications have confirmed the association between the lupus anticoagulant and pregnancy complications.[1-5] Moreover, a high dose of prednisone (40 to 60 mg/day) in combination with aspirin (75 mg/day) seems to improve the outcome in pregnant women with a bad obstetric history involving the lupus anticoagulant. However, this high dose of steroids has been associated with a number of complications.

We now have complete follow-up of three women with lupus anticoagulant, in whom all eight previous pregnancies had been unsuccessful. Administration of prednisone in a dose sufficient to suppress the lupus anticoagulant activity (10 to 20 mg/day) combined with aspirin (20 mg/day) resulted in the birth of a normal weight and healthy term newborn infant in all three cases. There were no major complications in the corticosteroid therapy. Three more cases are currently being treated in the same way with a normal evolution of pregnancy as of this date.

There is no doubt that the lupus anticoagulant is an important entity in reproductive failure and that the preliminary results of therapeutic intervention are promising. However, the pathophysiologic background needs further clarification. In addition, controlled multicenter prospective studies on treatment need to be done to prevent growing confusion and controversy.[6] These studies must be well designated with regard to patient collection and treatment protocol. We suggest that groups interested in initiating or contributing to such studies identify themselves and exchange protocols.

A sonographic sign for fetal Down's syndrome

To the Editors:

We have read with interest the report by Benacerraf et al. (A sonographic sign for the detection in the second trimester of the fetus with Down's syndrome. Am J Obstet Gynecol 1985;151:1078-9) identifying increased skin or soft tissue thickening at the neck as a sign indicating a high risk for Down's syndrome in the fetus. In their introductory sentences the authors convey the idea that this sign is the sole sonographic feature accompanying this syndrome, but there are many reports showing the relationship between Down's syndrome and a large number of echographic findings. Tchobroutsky et al.[1] showed trisomy 21 to be correlated with early (before week 20) fetal growth delay, an association which we recently observed as well. We have seen brachycephaly in Down's syndrome, and Collet et al.[2] found an abnormal biparietal/femur length proportion that was caused by femoral shortness occurring before week 20 in trisomy 21. Finally, we have repeatedly pointed to the high rate of association of trisomy 21 with duodenal atresia (100% in our experience), whereas this association is much less frequently

Table I. Echographic features associated with trisomy 21

Maternal age (yr)	*Gravidity/parity*	*Echographic features*
31	4/2	Low profile growth
43	15/12	Double-bubble image, hydramnios, duodenal atresia
18	1/0	Double-bubble image, hydramnios, duodenal atresia, hydrothorax
40	2/1	Double-bubble image, hydramnios, duodenal atresia
33	4/2	Double-bubble image, hydramnios, duodenal atresia, hydrothorax
21	1/0	Early growth delay

found together with the other forms of intestinal atresia.[3, 4]

In our series of more than 80 echographically diagnosed fetal malformations, 16 were intestinal malformations and abdominal wall defects. Of these 16, two were oesophageal atresias, one was jejunoileal atresia, and four were duodenal atresias, all of the last four occurring in trisomy 21 babies. One trisomy 21 baby showed early growth retardation and another low profile growth. Thus, of our trisomy 21 fetuses, six displayed echographic features related to this condition (Table I).

Relative placental size in growth-retarded infants

To the Editors:

In a recent study of infants born to women with preeclampsia, Teasdale suggested that placental growth was not retarded as the placental weight to infant weight ratio was similar to that found in normal control infants (Histomorphometry of the human placenta in maternal preeclampsia. AM J OBSTET GYNECOL 1985; 152:25-31). However, this conclusion may be misleading because of the choice of infant weight as the denominator in assessing relative placental weight. The birth weight of the five study infants was more depressed than their crown-heel length or head circumference, suggesting that they were wasted. This proposed loss of soft tissue is supported by a calculated mean ponderal index of 2.26 in the study infants compared to 2.56 in the control infants. A loss of body weight resulting from wasting would tend to keep the placental weight/infant weight ratio normal, as has been argued previously.[1, 2]

It is advocated that infant length or head circumference, which are more stable measurements of infant size at birth, are preferable denominators when assessing relative placental size. For example, the calculated mean placental weight/infant length ratio for the study and control infants is 9.06 and 9.23, respectively. This difference strongly suggests that infants born to women with preeclampsia may indeed have relatively underweight placentas.

Reply

To the Editors:

I appreciate Dr. Woods' interest in my paper, and I understand his comments concerning the use of other denominators than fetal weight to assess relative placental size. However, in the case of this study Dr. Wood has misinterpreted the data, and therefore his comments are not relevant to the conclusions raised by this investigation. For example, the ratios of placental and parenchymal weights, total trophoblast nuclei content, total villous and capillary surface areas, and intervillous space volume to fetal weight were all significantly "higher" in the study group compared to the control group (Table III). In contrast, the placental weight/infant length ratios for the study and control infants were 9.07 ± 0.72 (mean $\pm$ SD) and 9.23 ± 0.97 ($p > 0.05$), respectively. Therefore, in contrast to Dr. Woods' comment, these results suggest that placental growth was not retarded either in absolute or in relative values in the study group of preeclamptic mothers reported in this paper.

The College of Physicians & Surgeons

The Department of Obstetrics & Gynecology of the College of Physicians & Surgeons and The Presbyterian Hospital

GYNECOLOGIC SURGICAL FILM FESTIVAL

September 18 & 19, 1986 (Thursday & Friday)

at the St. Regis-Sheraton Hotel, New York, New York

Conference Director: MARVIN H. TERRY GRODY, MD, FACOG *Conference Chairman:* RAYMOND M. McCAFFREY, MD, FACOG

14 Credit Hours, Category 1, A.M.A.'s Physician's Recognition Award; 14 Cognates, Formal Learning, A.C.O.G.

Of primary interest to the generalist in gynecology are the regularly occurring benign situations which may be amenable to surgical correction. This conference is designed to address these situations through the presentation of motion pictures, of *state-of-the-art* quality, of a variety of surgical procedures that should be within the capabilities of the operating gynecologist. The filmed operations will have been performed by each of the presentors, demonstrating their own special techniques. Commentary by the operating surgeon and a question-and-answer period will follow each film showing.

PROGRAM PARTICIPANTS

JAMES L. BREEN, MD, FACOG, FACS
MARVIN H. TERRY GRODY, MD, FACOG
JOHN H. ISAACS, MD, FACOG
RAYMOND M. McCAFFREY, MD, FACOG
DAVID H. NICHOLS, MD, FACOG, FACS

CLINICAL GYNAECOLOGICAL ONCOLOGY

Edited by John H. Shepherd, F.R.C.S., M.R.C.O.G. and John M. Monaghan, M.B., F.R.C.S.(Ed.), F.R.C.O.G.; with 18 contributors
Written with a primarily clinical bias, this title emphasizes the practical management of your patient. Contents include: Epidemiology and etiology in gynecological malignancy; Pathology and Management of CIN, VAIN, and VIN; Cervical cancer: the surgical management of early stage disease; the management of advanced and recurrent cervical cancer by pelvic exenteration; Chemotherapy in ovarian carcinoma and other gynecological tumors, and more.
1985. 436 pages, with 119 illustrations. (B-4567-0) $54.75

New!

CLINICAL DIAGNOSTIC ULTRASOUND

By Ellis Barnett, F.R.C.P. and Patricia Morley, F.R.C.R.
This comprehensive textbook on diagnostic ultrasound covers all the main systems, with emphasis placed on the clinical application of diagnostic ultrasound in everyday practice. With contributions from an eminent team of authors, it provides you with not only a valuable text, but a useful general reference.
Contents include: Instrumentation; Heart; Vascular system; Small part scanning; Abdomen, gastrointestinal tract and peritoneum; Liver and pancreas; Renal tract; Gynaecology; Obstetrics; Paediatrics; and more
February, 1986. Approx. 400 pages, 800 illustrations. (B-0482-6) About $201.95

New 2nd Edition!

HUMAN EMBRYOLOGY

By F. Beck, D.Sc., M.D., Ch.B.; D.B. Moffat, M.D., F.R.C.S.; and D.P. Davies, B.Sc., M.B., D.C.H., D.Obst., F.R.C.P.
This new edition has been completely updated, with emphasis on clinical details of inherited anomalies. Chapters on developmental anatomy give you a clear account of the formation of all the body systems, set against a background of general reproductive physiology and anatomy. In addition, the sections on growth and development and their disorders have been greatly expanded—with emphasis on their clinical importance.
1986. 383 pages, 204 illustrations. (B-0557-1) $18.95

New!

MEDICAL GYNAECOLOGY

Edited by M.C. Macnaughton, M.D., F.R.C.O.G., F.R.C.P.(Glas.), F.R.S.E.; with 10 contributors
This book underlines the breadth of important gynecolcgic issues—research into endocrine, immunological and psychological issues in the health of women, matched only by the concern of your patients themselves. If you pick it up, you won't put it down!
Contents include: Sexual dysfunction; The recognition and management of the fluid retention and premenstrual syndromes; Genetic counselling; Pregnancy counselling; Infertility; Artificial insemination by donor (AID) and artificial insemination by husband (AIH); Genitourinary medicine; Family planning; and more
1985. 282 pages, illustrated. (B-3194-7) $32.95

Contemporary Issues in Fetal and Neonatal Medicine Series: PERINATAL BRAIN DAMAGE

By Karen E. Pape, M.D. and Jonathan S. Wigglesworth, M.D., F.R.C.Path.
Here you'll find all that's important in understanding and managing perinatal brain damage. Expert contributors provide you with a practical discussion of the causes and treatment of perinatal brain damage.
Chapters Include: CT—the State of the Art; Ultrasound—the State of the Art; Magnetic Resonance Imaging and New Imaging Techniques; Birth Asphyxia—Scientific Studies and Clinical Problems; Intraventricular Hemorrhage; Cerebral Blood Flow Management; Diagnosis and management of hydrocephalus; Follow-up of neonatal brain injured children
March, 1986. Approx. 250 pages. (A-3787-2) About $25.00

New!

BREAST CANCER: Treatment and Progress

Edited by B.A. Stoll, F.R.C.R., F.F.R.
This book examines, in a critical and realistic manner, the final goals in any treatment of breast cancer. It looks at the chances of achieving these goals, the price to be paid by your patient and the prospects of more effective treatment likely to become available in the foreseeable future. Instead of being concerned with comparisons of different types of therapy in large groups of patients, this book places the emphasis firmly on the individual patient.

ORTHO-NOVUM 7/7/7

TRADEMARK

Tablets

(norethindrone/ethinyl estradiol)

Enhanced patient compliance

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 0.05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

A choice that's right

for both of you.

- 29% lower progestin dose than 1/35[1]
- Full-cycle breakthrough bleeding control equal to 1/35[1]
- Unique "low-higher-low" phasing for extra mid-cycle protection.
- Norethindrone-based for low metabolic impact[2,3]
- Supplied in the patient-preferred Wallette™ pill dispenser.[4]

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

1. 1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. BTB comparisons are based on the first three cycles of use. Data available from Syntex Laboratories, Inc.
2. Wynn V, Niththyananthan R: The effect of progestins in combined oral contraceptives on serum lipids with special reference to high-density lipoproteins. *Am J Obstet Gynecol* 142:766-772, 1982.
3. Wynn V: Effect of duration of low-dose oral contraceptive administration on carbohydrate metabolism. *Am J Obstet Gynecol* 142:739-746, 1982.
4. In an independent survey the Wallette™ pill dispenser was preferred to the Ortho Dialpak by 7 out of 10 prospective OC patients. Data available from Syntex Laboratories, Inc.

TRI-NORINYL® TABLETS

(NORETHINDRONE AND ETHINYL ESTRADIOL)

Because your common goal is confidence.

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 80 21-Day Tablets (norethindrone 1 mg with mestranol 0.08 mg)
NORINYL® 1 + 80 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.08 mg tablets followed by 7 inert tablets)
NORINYL® 2 mg Tablets (norethindrone 2 mg with mestranol 0.1 mg)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM:* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.
MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34–5/100,000; ages 35-44–33/100,000; ages 45-49–140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34–1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over–1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS–RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A–Use associated with very high risk.
B–Use associated with high risk.
C–Use associated with moderate risk.
D–Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones–estrogenic and progestational agents–during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) then among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences,* or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned.
Precautions *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings.
Adverse Reactions An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms, (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

MILES
Miles Pharmaceuticals

One tablet is the total treatment

Mycelex®-G 500 mg

(clotrimazole) Vaginal Tablet

INDICATIONS: Mycelex®-G 500 mg Vaginal Tablets are indicated for the local treatment of vulvovaginal candidiasis when one day therapy is felt warranted. In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended. The diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis, *Trichomonas* and *Gardnerella (Haemophilus) vaginalis*, should be ruled out by appropriate laboratory methods.

CONTRAINDICATIONS: Mycelex®-G 500 mg Vaginal Tablets are contraindicated in women who have shown hypersensitivity to any components of the preparation.

WARNINGS: None.

PRECAUTIONS: If there is a lack of response to Mycelex®-G 500 mg Vaginal Tablets, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens before instituting another course of antimycotic therapy.

CARCINOGENESIS: No long term studies in animals have been performed to evaluate the carcinogenic potential of Mycelex®-G 500 mg Vaginal Tablets intravaginally. A long term study in rats (Wistar strains) where clotrimazole was administered orally provided no indication of carcinogenicity.

USAGE IN PREGNANCY: PREGNANCY CATEGORY B: The disposition of ^{14}C-clotrimazole has been studied in humans and animals. Clotrimazole is poorly absorbed following intravaginal administration to humans, whereas it is rather well absorbed after oral administration.

In clinical trials, use of vaginally applied clotrimazole in pregnant women in their second and third trimesters has not been associated with ill effects. There are, however, no adequate and well-controlled studies in pregnant women during the first trimester of pregnancy.

Studies in pregnant rats given repeated intravaginal doses up to 100 mg/kg/day have revealed no evidence of harm to the fetus due to clotrimazole.

Repeated high oral doses of clotrimazole in rats and mice ranging from 50 to 120 mg/kg resulted in embryotoxicity (possibly secondary to maternal toxicity), impairment of mating, decreased litter size and number of viable young and decreased pup survival to weaning. However, clotrimazole was not teratogenic in mice, rabbits and rats at oral doses up to 200, 180 and 100 mg/kg, respectively. Oral absorption in the rat amounts to approximately 90% of the administered dose.

Because animal reproduction studies are not always predictive of human response, this drug should be used only if clearly indicated during the first trimester of pregnancy.

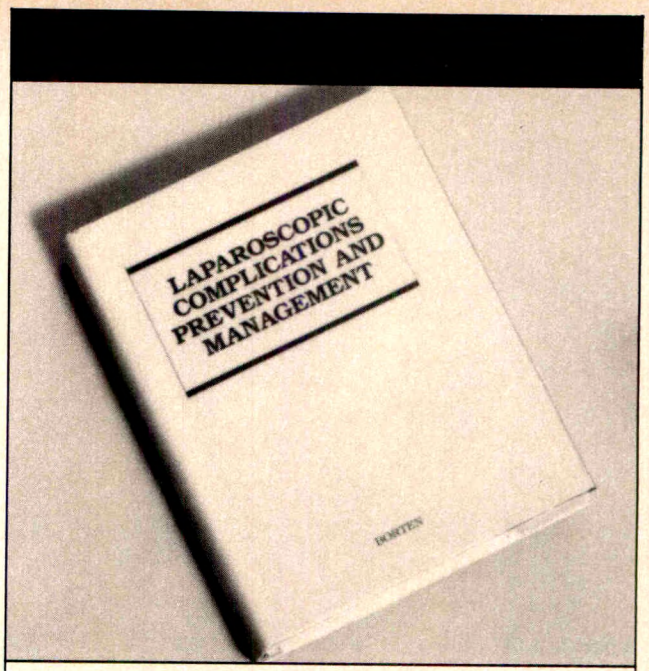
ADVERSE REACTIONS: Of 297 patients in double-blind studies with the 500 mg vaginal tablet, 3 of 149 patients treated with active drug and 3 of 148 patients treated with placebo reported complaints during therapy that were possibly drug related. In the active drug group, vomiting occurred in one patient, vaginal soreness with coitus in another, and complaints of vaginal irritation, itching, burning and dyspareunia in the third patient. In the placebo group, clitoral irritation occurred in one patient and dysuria, described as remotely related to drug, in the other. A third patient in the placebo group developed bacterial vaginitis which the investigator classed as possibly related to drug.

Eighteen (1.6%) of the 1116 patients treated with Mycelex®-G in other formulations in double-blind studies reported complaints during therapy that were possibly drug-related. Mild burning occurred in six patients while other complaints such as skin rash, itching, vulval irritation, lower abdominal cramps and bloating, slight cramping, slight urinary frequency, and burning or irritation in the sexual partner, occurred rarely.

OVERDOSAGE: No data available.

DRUG ABUSE AND DEPENDENCE: Drug abuse and dependence with Mycelex®-G 500 mg Vaginal Tablets has not been reported.

DOSAGE AND ADMINISTRATION: The recommended dose is one tablet inserted intravaginally one time only, preferably at bedtime. In the event of treatment failure, that is, persistence of signs and symptoms of vaginitis after five days, other pathogens commonly responsible for vaginitis should be ruled out before instituting another course of antimycotic therapy.



HOW SUPPLIED: Mycelex®-G 500 mg Vaginal Tablets are white, bullet shaped, uncoated tablets, coded with Miles on one side and 097 on the other, supplied as a single 500 mg tablet with plastic applicator and patient instructions.

LAPAROSCOPIC COMPLICATIONS: Prevention and Management

By Max Borten, M.D.

Written by a recognized authority, this book gives you first-hand knowledge on both medical and surgical management of laparoscopic complications. From indications and contraindications, it guides you through detailed discussions of failures of procedure and equipment, to the medicolegal aspects of both the procedure and its complications. Intraoperative slides and line drawings fully illustrate the text. Once you see it, you won't let it go! Order your copy today! April, 1986. Approx. 304 pages. (D-0723-X) Mosby distributes this B.C. Decker, Inc. publication. About $68.00

OUTLINE OF CONTENTS: INTRODUCTION: Instrumentation, Technique, Diagnostic Indications for Laparoscopy, Operative Indications for Laparoscopy, Laparoscopic Sterilization, Contraindications to Laparoscopy, Nongynecologic Indications for Laparoscopy, Choice of Anesthesia, Circulatory Changes, Respiratory Changes, Postoperative Recovery COMPLICATIONS: Equipment Failure, Procedural Failure, Complications of Anesthesia, Complications of Pneumoperitoneum, Complications of Trocar Insertion, Vascular Injuries, Intestinal Tract Injuries, Urinary Tract Injuries, Tegumentary Injuries, Complications due to Infection, Complications of Sterilization, Electrical Complications, Postoperative Complications, Medicolegal Aspects of Laparoscopy APPENDIX: Translaparoscopic Photography

Less withdrawal bleeding: another reason for OGEN® (estropipate)

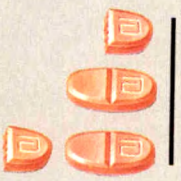
In a 3-month comparative trial[1] OGEN and a progestogen* induced less withdrawal bleeding than did conjugated estrogens and a progestogen.*

It's just one more reason why OGEN is so easy to start with, and so easy to stay with.

Percentage of women without withdrawal bleeding, taking either OGEN 1.25 or conjugated estrogens 0.625 mg [1]

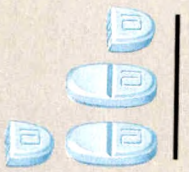
$p<0.05$. *Adapted from Wren and Routledge, 1982*[1]

*Both regimens were given 24 days out of 30, with levonorgestrel 0.03 mg, a progestogen, added from the 15th to 24th day.

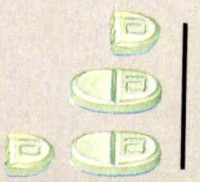


OGEN®
(estropipate)

Only estrone. Identical to the body's own.



Scored tablets make precise dosing easy



OGEN .625
(estropipate 0.75 mg, calculated as sodium estrone sulfate 0.625 mg)

OGEN 1.25
(estropipate 1.5 mg, calculated as sodium estrone sulfate 1.25 mg)

OGEN 2.5
(estropipate 3 mg, calculated as sodium estrone sulfate 2.5 mg)

OGEN 5
(estropipate 6 mg, calculated as sodium estrone sulfate 5 mg)

OGEN tablets are scored so you can adjust dosage without writing a new prescription. It's another reason more physicians are prescribing OGEN.

OGEN®
(estropipate)

Only estrone. Identical to the body's own.

See adjacent page for brief summary of prescribing information.

OGEN®

ESTROPIPATE TABLETS, USP

Tablets

WARNING:

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. OGEN SHOULD NOT BE USED DURING PREGNANCY.

According to some investigators, the use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. Studies have reported that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. In one of these studies, this risk was estimated as not greater than 4 per 1000 exposures. Furthermore, there are reports that a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these reported changes are histologically benign, the investigators have not determined whether they are precursors of adenocarcinoma.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies in the offspring, including heart defects and limb reduction defects. One case control study estimated a 4.7 fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. OGEN has not been studied for these uses, and therefore should not be used during pregnancy. There is no evidence from well controlled studies that progestogens are effective for these uses.

If OGEN (estropipate tablets) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the question of continuation of the pregnancy should be addressed.

INDICATIONS AND USAGE

The cyclic administration (See "DOSAGE AND ADMINISTRATION" section) of OGEN (estropipate tablets) is indicated for the treatment of estrogen deficiency associated with:

1. Moderate to severe *vasomotor* symptoms of menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.

OGEN (ESTROPIPATE TABLETS) HAS NOT BEEN TESTED FOR EFFICACY FOR ANY PURPOSE DURING PREGNANCY. SINCE ITS EFFECT UPON THE FETUS IS UNKNOWN, IT CANNOT BE RECOMMENDED FOR ANY CONDITION DURING PREGNANCY (SEE BOXED WARNING).

CONTRAINDICATIONS

OGEN should not be used in women with any of the following conditions:

1. Known or suspected cancer of the breast.
2. Known or suspected estrogen-dependent neoplasia.
3. OGEN may cause fetal harm when administered to a pregnant woman. OGEN is contraindicated in women who are or may become pregnant (See Boxed Warning).
4. Undiagnosed abnormal genital bleeding.
5. Active thrombophlebitis or thromboembolic disorders.
6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. *Induction of malignant neoplasms.* Long-term continuous administration of natural and synthetic estrogens in certain animal species has been reported by some investigators to increase the frequency of carcinomas of the breast, cervix, vagina, and liver. There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning).

At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. Therefore, caution should be exercised when administering estrogens to women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. Careful breast examinations should be performed periodically.

2. *Gall bladder disease.* A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens, similar to the 2-fold increase previously noted in users of oral contraceptives. In the case of oral contraceptives, the increased risk appeared after two years of use.

3. *Effects similar to those caused by estrogen-progestogen oral contraceptives.* There are several serious adverse effects of oral contraceptives, most of which have not, up to now, been documented as consequences of postmenopausal estrogen therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women. It would be expected that the larger doses of estrogen used to treat postpartum breast engorgement would be more likely to result in these adverse effects, and, in fact, it has been shown that there is an increased risk of thrombosis in women receiving estrogens for postpartum breast engorgement.

a. *Thromboembolic disease.* It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism; it should also be discontinued during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. *Hepatic adenoma.* Benign hepatic adenomas appear to be associated with the use of oral contraceptives. Although benign, and rare, these may rupture and cause death through intraabdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations but should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The relationship of this malignancy to these drugs is not known at this time.

c. *Elevated blood pressure.* Increased blood pressure is not uncommon in women using oral contraceptives. There is now a report that this may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used.

d. *Glucose tolerance.* A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. *Hypercalcemia.* Administration of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

PRECAUTIONS

A. General Precautions.

1. A complete medical and family history should be taken prior to the initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.

2. Fluid retention — Estrogens may cause some degree of fluid retention. Therefore, patients with conditions such as epilepsy, migraine, and cardiac or renal dysfunction, which might be influenced by this factor, require careful observation.

3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc.

4. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.

5. Preexisting uterine leiomyomata may increase in size during estrogen use.

6. The pathologist should be advised of the patient's use of estrogen therapy when relevant specimens are submitted.

7. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving estrogen-containing oral contraceptive therapy. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.

8. Estrogens may be poorly metabolized in patients with impaired liver function and they should be administered with caution in such patients.

9. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency.

B. Information for the Patient. See text of Patient Package Insert which appears after PHYSICIAN REFERENCES.

C. Drug Interactions. The concomitant use of any drugs which can induce hepatic microsomal enzymes with estrogens may produce estrogen levels which are lower than would be expected from the dose of estrogen administered.

The use of *broad spectrum antibiotics* which profoundly effect intestinal flora may influence the absorption of steroidal compounds including the estrogens.

Diabetics receiving *insulin* may have increased insulin requirements when receiving estrogens.

Laboratory Test Interference. Certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following similar changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Abnormal glucose tolerance test results.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

D. Carcinogenesis. Studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods (see Boxed Warning). At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. (See "WARNINGS" section.)

E. Pregnancy. Pregnancy Category X. See "CONTRAINDICATIONS" section and Boxed Warning.

F. Nursing Mothers. Estrogens have been reported to be excreted in human breast milk. Caution should be exercised when OGEN is administered to a nursing woman.

G. Pediatric Use. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete.

ADVERSE REACTIONS

(See Warnings regarding reports of possible induction of neoplasia, unknown effects upon the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions in decreasing order of severity within each category have been reported with estrogenic therapy, including oral contraceptives:

1. *Genitourinary system.*
Increase in size of uterine fibromyomata.
Vaginal candidiasis.
Cystitis-like syndrome.
Dysmenorrhea.
Amenorrhea during and after treatment.
Change in cervical eversion and in degree of cervical secretion.
Breakthrough bleeding, spotting, change in menstrual flow.
Premenstrual-like syndrome.
2. *Breast.*
Tenderness, enlargement, secretion.
3. *Gastrointestinal.*
Cholestatic jaundice.
Vomiting, nausea.
Abdominal cramps, bloating.
4. *Skin.*
Hemorrhagic eruption.
Erythema nodosum.
Erythema multiforme.
Hirsutism.
Chloasma or melasma which may persist when drug is discontinued.
Loss of scalp hair.
5. *Eyes.*
Steepening of corneal curvature.
Intolerance to contact lenses.
6. *CNS.*
Chorea.
Mental depression.
Migraine, dizziness, headache.
7. *Miscellaneous.*
Aggravation of porphyria.
Edema.
Reduced carbohydrate tolerance.
Increase or decrease in weight.
Changes in libido.

OVERDOSAGE

Numerous reports of ingestion of large doses of estrogen-containing oral contraceptives by young children indicate that serious ill effects do not occur. Overdosage of estrogen may cause nausea and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION

1. *Given cyclically for short-term use:*

For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., 3 weeks on and 1 week off).

Attempts to discontinue or taper medication should be made at 3 to 6 month intervals.

Usual dosage ranges:

Vasomotor symptoms —One OGEN .625 Tablet to one OGEN 5 Tablet per day. The lowest dose that will control symptoms should be chosen. If the patient has not menstruated within the last two months or more, cyclic administration is started arbitrarily. If the patient is menstruating, cyclic administration is started on day 5 of bleeding.

Atrophic vaginitis and kraurosis vulvae — One OGEN .625 Tablet to one OGEN 5 Tablet daily, depending upon the tissue response of the individual patient. The lowest dose that will control symptoms should be chosen. Administer cyclically.

2. *Given cyclically:*

Female hypogonadism; female castration; primary ovarian failure.

Usual dosage ranges:

Female hypogonadism — A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. The lowest dose that will control symptoms should be chosen. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium. If satisfactory withdrawal bleeding does not occur, an oral progestogen may be given in addition to estrogen during the third week of the cycle.

Female castration and primary ovarian failure —A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. Adjust dosage upward or downward according to severity of symptoms and response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED

OGEN (estropipate tablets, USP) is supplied as OGEN .625 (0.75 mg estropipate), yellow tablets, **NDC** 0074-3943-04; OGEN 1.25 (1.5 mg estropipate), peach-colored tablets, **NDC** 0074-3946-04; OGEN 2.5 (3 mg estropipate), blue tablets, **NDC** 0074-3951-04; and OGEN 5 (6 mg estropipate), light green tablets, **NDC** 0074-3958-13. Tablets of all four dosage levels are standardized to provide uniform estrone activity and are grooved (Divide-Tab®) to provide dosage flexibility. All tablet sizes of OGEN are available in bottles of 100.

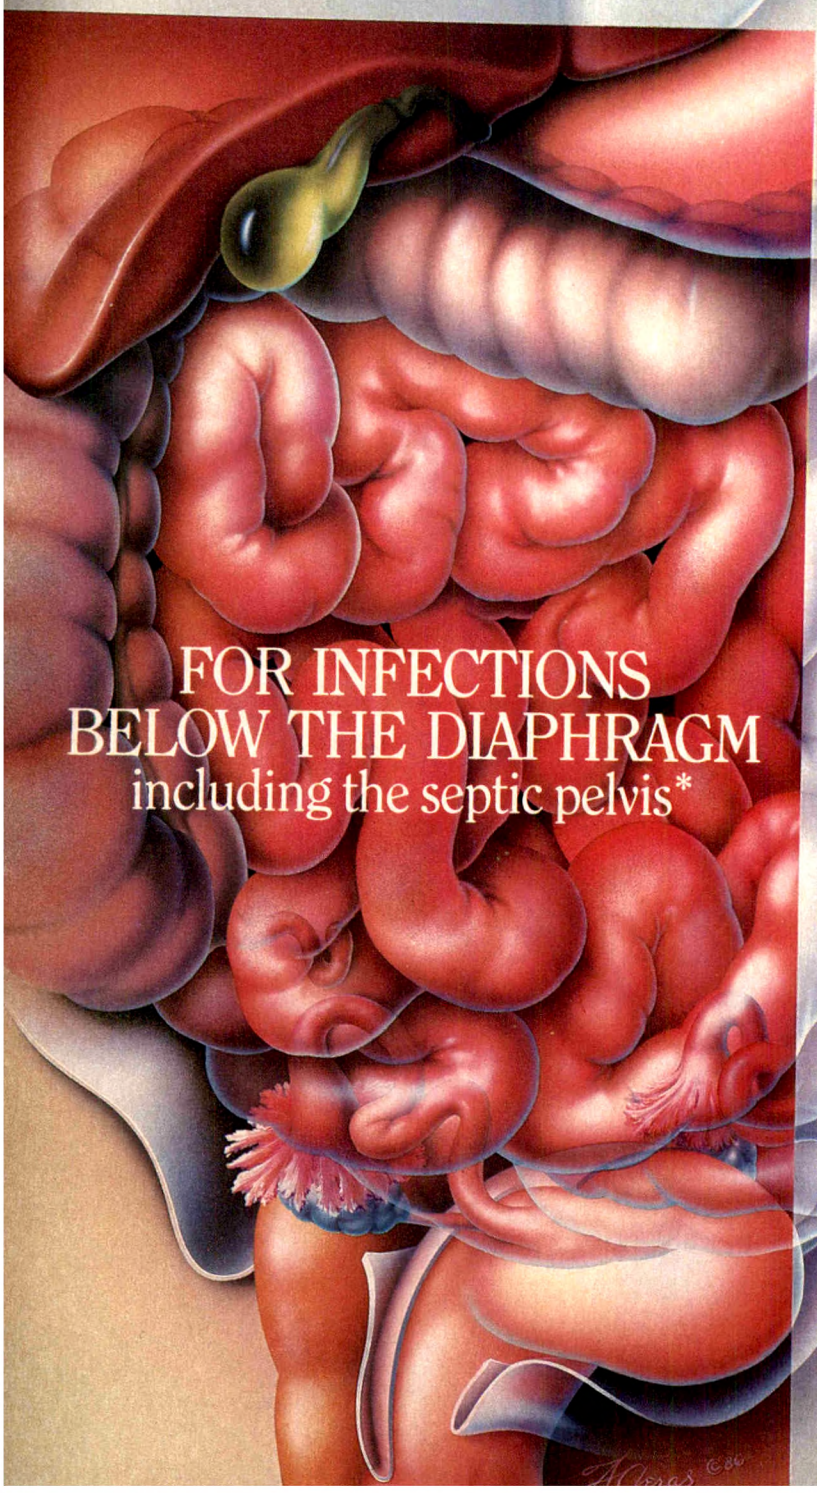
Abbott Pharmaceuticals, Inc.
North Chicago, Illinois 60064



Outstanding mixed aerobic/anaerobic coverage

Cefizox® IM IV

brand of sterile

ceftizoxime sodium

Injection: 1 and 2 gram vials

FOR INFECTIONS BELOW THE DIAPHRAGM including the septic pelvis*

- **B.I.D. Dosing† for All but Life-Threatening Infections**
- **Clinical Cure Unsurpassed By Clindamycin/Tobramycin[1]**

A recent, prospective, randomized, comparative trial demonstrated that 'Cefizox' was equal to clindamycin/tobramycin in the treatment of intra-abdominal infections.

- **Better Gram-negative and *Bacteroides* Coverage Than Mefoxin® (cefoxitin)‡**

Aerobic Organisms[2] (number of strains)	CEFIZOX® (ceftizoxime) MIC_{90}	MEFOXIN® (cefoxitin) MIC_{90}
Gram-Negative	**mcg./ml.**	**mcg./ml.**
Escherichia coli (40)	0.04	6.3
Klebsiella pneumoniae (32)	0.05	25
Enterobacter aerogenes (16)	0.12	>400
Enterobacter cloacae (16)	0.8	400
Proteus sp. (indole positive) (26)	6.3	12.5
Citrobacter sp. (32)	0.2	400
Gram-Positive	**mcg./ml.**	**mcg./ml.**
Staphylococcus aureus (16)	3.1	3.1

Bacteroides species[3] (number of strains)	CEFIZOX® (ceftizoxime) MIC_{90}	MEFOXIN® (cefoxitin) MIC_{90}
B. fragilis (55)	8 mcg./ml.	16 mcg./ml.
B. ovatus (17)	16 mcg./ml.	64 mcg./ml.
B. thetaiotaomicron (13)	64 mcg./ml.	32 mcg./ml.
B. distasonis (12)	8 mcg./ml.	32 mcg./ml.
B. vulgatus (3)	8 mcg./ml.	16 mcg./ml.

* Due to susceptible strains of indicated organisms.
† Dosage in renally compromised patients may require adjustment. Please see complete prescribing information.
‡ *In vitro* activity does not necessarily imply *in vivo* effectiveness.

Please consult last page of this advertisement for brief summary of prescribing information.

Cefizox®

brand of

sterile ceftizoxime sodium and ceftizoxime sodium injection

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

'Cefizox' is indicated in the treatment of infections due to susceptible strains of the microorganisms listed below:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Klebsiella* sp.; *Proteus mirabilis; Escherichia coli; Haemophilus influenzae* including ampicillin-resistant strains; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Serratia* sp.; *Enterobacter* sp.; and *Bacteroides* sp.

URINARY TRACT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Pseudomonas* sp. including *Ps. aeruginosa; Proteus mirabilis; P. vulgaris; Providencia rettgeri* (formerly *Proteus rettgeri*) and *Morganella morganii* (formerly *Proteus morganii*); *Klebsiella* sp.; *Serratia* sp. including *S. marcescens; Enterobacter* sp.

GONORRHEA. Uncomplicated cervical and urethral gonorrhea caused by *Neisseria gonorrhoeae.*

INTRA-ABDOMINAL INFECTIONS caused by *Escherichia coli; Staphylococcus epidermidis; Streptococcus* sp. (excluding enterococci); *Enterobacter* sp.; *Klebsiella* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

SEPTICEMIA caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Bacteroides* sp. including *B. fragilis; Klebsiella* sp.; and *Serratia* sp.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Staphylococcus epidermidis; Escherichia coli; Klebsiella* sp.; *Streptococcus* sp. including *Streptococcus pyogenes* (group A beta-hemolytic), but excluding enterococci; *Proteus mirabilis; Serratia* sp.; *Enterobacter* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

BONE AND JOINT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Streptococcus* sp. (excluding enterococci); *Proteus mirabilis; Bacteroides* sp.; and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

MENINGITIS caused by *Haemophilus influenzae*. 'Cefizox' has also been used successfully in the treatment of a limited number of pediatric and adult cases of meningitis caused by *Streptococcus pneumoniae.*

'Cefizox' has been effective in the treatment of seriously ill, compromised patients, including those who were debilitated, immunosuppressed or neutropenic.

Many infections caused by aerobic gram-negative organisms and by mixtures of organisms resistant to other cephalosporins, aminoglycosides, or penicillins respond to treatment with 'Cefizox'.

Because of the serious nature of some urinary tract infections due to *Ps. aeruginosa* and because many strains of *Pseudomonas* species are only moderately susceptible to 'Cefizox', higher dosage is recommended. Other therapy should be instituted if the response is not prompt.

Susceptibility studies on specimens obtained prior to therapy should be used to determine the response of causative organisms to 'Cefizox'. Therapy with 'Cefizox' may be initiated pending results of the studies; however, treatment should be adjusted according to study findings. In serious infections 'Cefizox' has been used concomitantly with aminoglycosides (see Precautions). Before using 'Cefizox' concomitantly with other antibiotics, the prescribing information for those agents should be reviewed for contraindications, warnings, precautions and adverse reactions. Renal function should be carefully monitored.

CONTRAINDICATIONS

'Cefizox' is contraindicated in persons who have shown hypersensitivity to cephalosporin antibiotics.

WARNINGS

BEFORE THERAPY WITH 'CEFIZOX' IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

***Pseudomembranous colitis* has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who developed diarrhea in association with antibiotic use.** Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of *Clostridia*. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro*. Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile.* Other causes of colitis should also be considered.

PRECAUTIONS

General: As with all broad-spectrum antibiotics, 'Cefizox' should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Although 'Cefizox' has not been shown to produce an alteration in renal function, renal status should be evaluated, especially in seriously ill patients receiving maximum dose therapy. As with any antibiotic, prolonged use may result in overgrowth of nonsusceptible organisms. Careful observation is essential; appropriate measures should be taken if superinfection occurs.

Drug Interactions: Although the occurrence has not been reported with 'Cefizox,' nephrotoxicity has been reported following concomitant administration of other cephalosporins and aminoglycosides.

Pregnancy: (Category B.) Reproduction studies have been performed in rats and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to 'Cefizox'. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery: Safety of 'Cefizox' use during labor and delivery has not been established.

Nursing Mothers: 'Cefizox' is excreted in human milk in low concentrations. Caution should be exercised when 'Cefizox' is administered to a nursing woman.

Infants and Children: Safety and efficacy in infants from birth to six months of age have not been established. In children six months of age and older, treatment with 'Cefizox' has been associated with transient elevated levels of eosinophils, SGOT, SGPT and CPK (creatine phospholkinase). The CPK elevation may be related to I.M. administration.

ADVERSE REACTIONS

Ceftizoxime is generally well tolerated; the *most* frequent adverse reactions (*greater than* 1%, but less than 5%) are: *Hypersensitivity*—Rash, pruritus, fever. *Hepatic*—Transient elevation in SGOT, SGPT and alkaline phosphatase. *Hematologic*—Transient eosinophilia, thrombocytosis. Some individuals have developed a positive Coombs test. *Local*—Injection site—Burning, cellulitis, phlebitis with I.V. administration, pain, induration, tenderness, paresthesia.

Less frequent adverse reactions (*less than* 1%) are: *Hypersensitivity*—Numbness has been reported rarely. *Hepatic*—Elevation of bilirubin has been reported rarely. *Renal*—Transient elevations of BUN and creatinine have been occasionally observed with ceftizoxime. *Hematologic*—Anemia, leukopenia, neutropenia and thrombocytopenia have been reported rarely. *Genitourinary*—Vaginitis has rarely occurred. *Gastrointestinal*—Diarrhea; nausea and vomiting have been reported occasionally. Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment. (See Warnings.)

HOW SUPPLIED

Cefizox (sterile ceftizoxime sodium, FSK) is supplied in vials equivalent to 1 gram or 2 grams of ceftizoxime; in "Piggyback" Vials for I.V. admixture equivalent to 1 gram or 2 grams of ceftizoxime.

Cefizox (ceftizoxime sodium injection, FSK) as a frozen, sterile, nonpyrogenic solution in plastic containers—supplied in 50 ml. single-dose containers equivalent to 1 gram or 2 grams of ceftizoxime, in 5% Dextrose (D5W). Do not store above -20°C.

'Cefizox' supplied as a frozen, sterile, nonpyrogenic solution in plastic containers is manufactured for Fujisawa SmithKline Corporation by Travenol Laboratories, Inc., Deerfield, IL 60015.

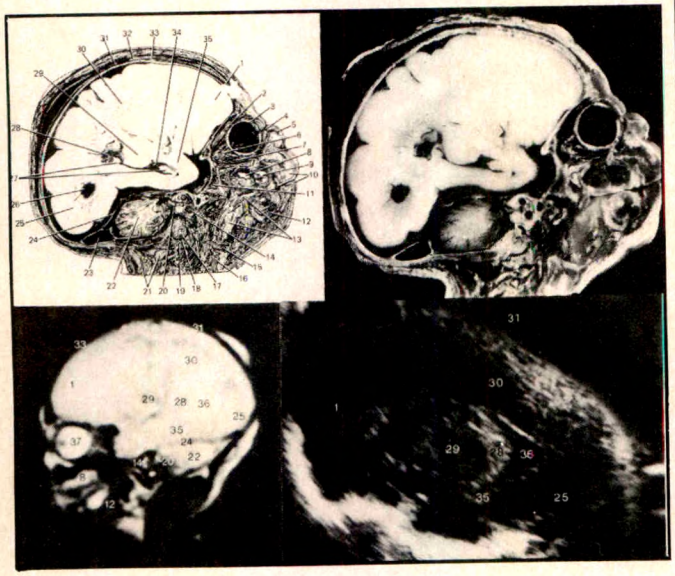
Atlas of Fetal Sectional Anatomy

With Ultrasound and Magnetic Resonance Imaging



Glenn Isaacson, MD; Marshall C. Mintz, MD; and Edmund S. Crelin, PhD, DSc

Here is the first comprehensive atlas of sectional anatomy for the fetus featuring:

- correlated anatomy and imaging
- transverse coronal and sagittal views
- a guide to development of the brain
- cardiac anatomy in standard planes of study
- over 280 illustrations of superb quality

At each level of section, fetal gross anatomy is correlated with in utero ultrasound and "ex utero" magnetic resonance images so that anatomic points may be compared. Such correlation is vital to obstetricians and radiologists who study the fetus using ultrasound, as it is difficult to interpret such scans without knowing the positions, size and shape of fetal structures. The clarity of the photographs, authoritative anatomic interpretations, and the anatomy-paired-with-image format makes this volume the essential reference for any obstetrician using ultrasound.

Ultrasound Diagnosis in Obstetrics and Gynecology

M. Hansmann, MD; B.-J. Hackelöer, MD; and A. Staudach, MD

Translated from the German by *T.C. Telger*
Co-editor of the English Edition: *B.K. Wittmann, MD*
With a foreword by *I. Donald*

World renowned experts in ultrasound diagnosis in obstetrics and gynecology bring you the most detailed and comprehensive atlas available on the subject. Here is a quick and precise reference-guide to your most pressing questions on:

- early pregnancy
- the sonoanatomy and biometry of the fetus
- the diagnosis of deformations
- the diagnosis of cycle dynamics
- the diagnosis of breast cancer

All areas are discussed in lucid and practical detail, with emphasis on clinical background, scientific basics, technical accuracy, anatomical correlation, clinical application, pathophysiology, and outcome data. This full coverage is supported by a wealth of documented personal experience, together with extensive pictorial and graphic material of outstanding quality. The book includes both a review of the literature and the historical background, and a look ahead to future trends and techniques. The English edition has been adapted to American standards with an additional contribution on biometry by P. Jeanty.

from the reviews of the German language edition:

"The book is very well written, combining clinical facts with imaging in a very successful fashion . . . It is an excellent introduction to US imaging in gynecology, emphasizing especially obstetrical US imaging. Even experienced ultrasonographers stand to gain from the perusal of the book because of the excellent illustrations." **—Radiology**

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England).

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manu-

script and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgements. Acknowledge only persons who have made substantive contributions to the study.

References. Limit of 16 references, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the U.S. National Library of Medicine in *Cumulated Index Medicus*. Journal titles should also conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper. For black and white illustrations, submit three sets of 5 by 7 inch (8 by 10 inch maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

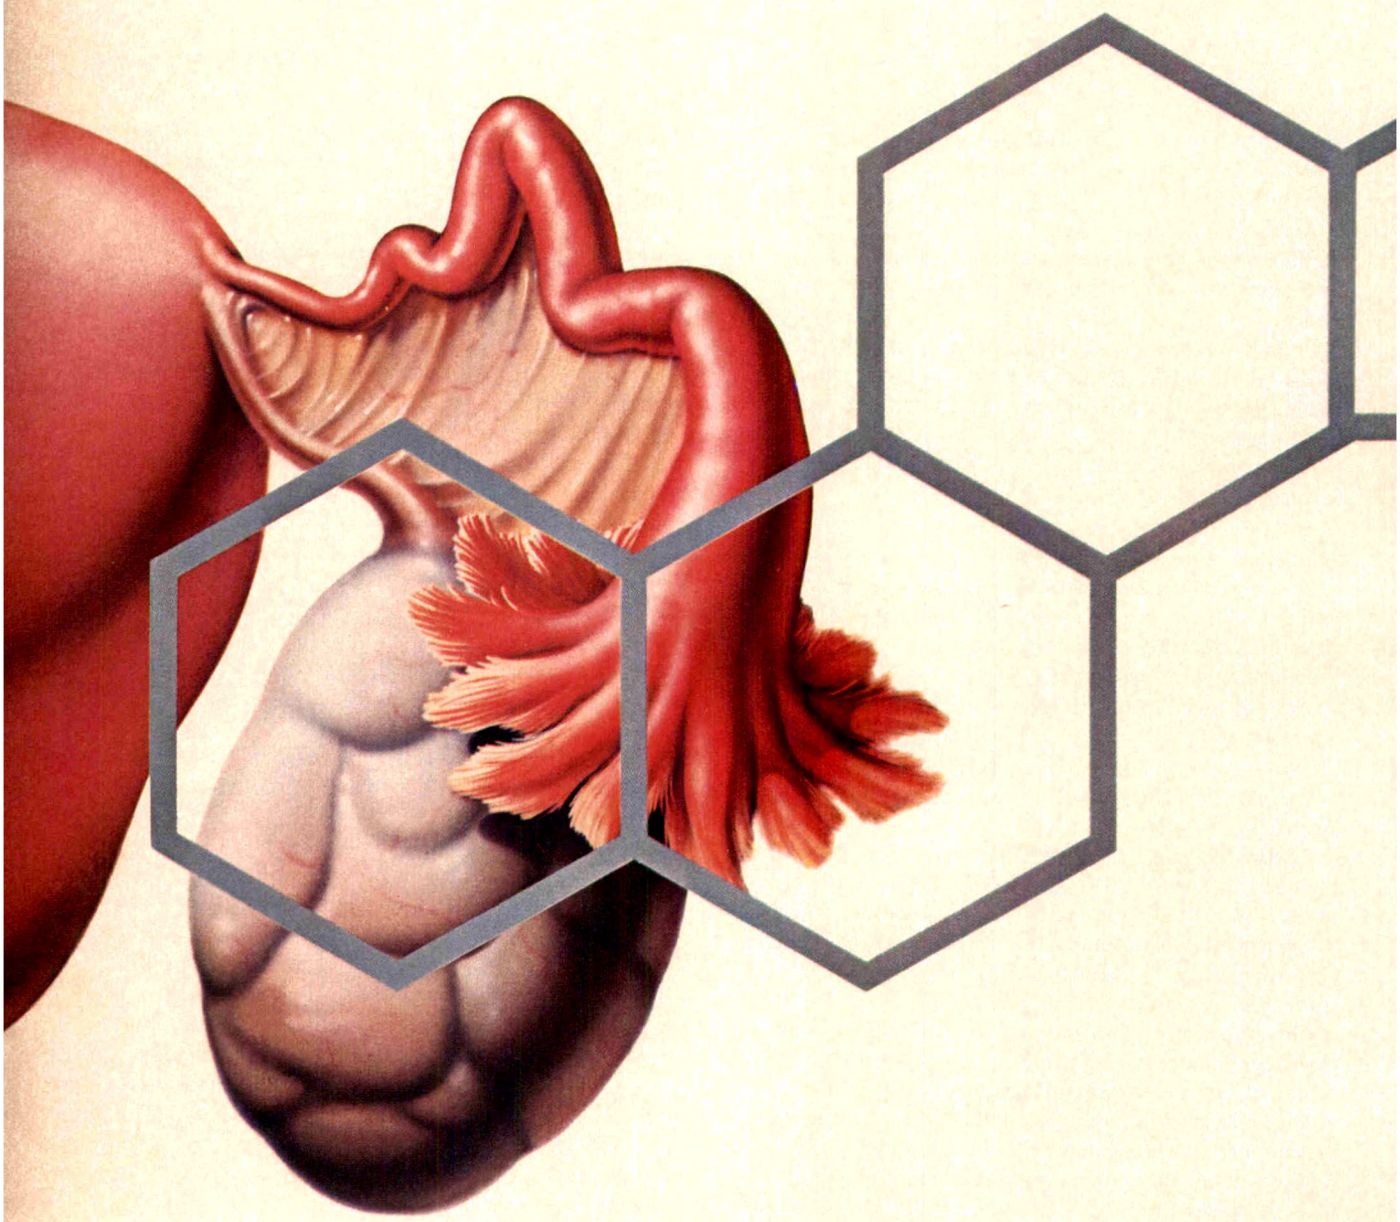
Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

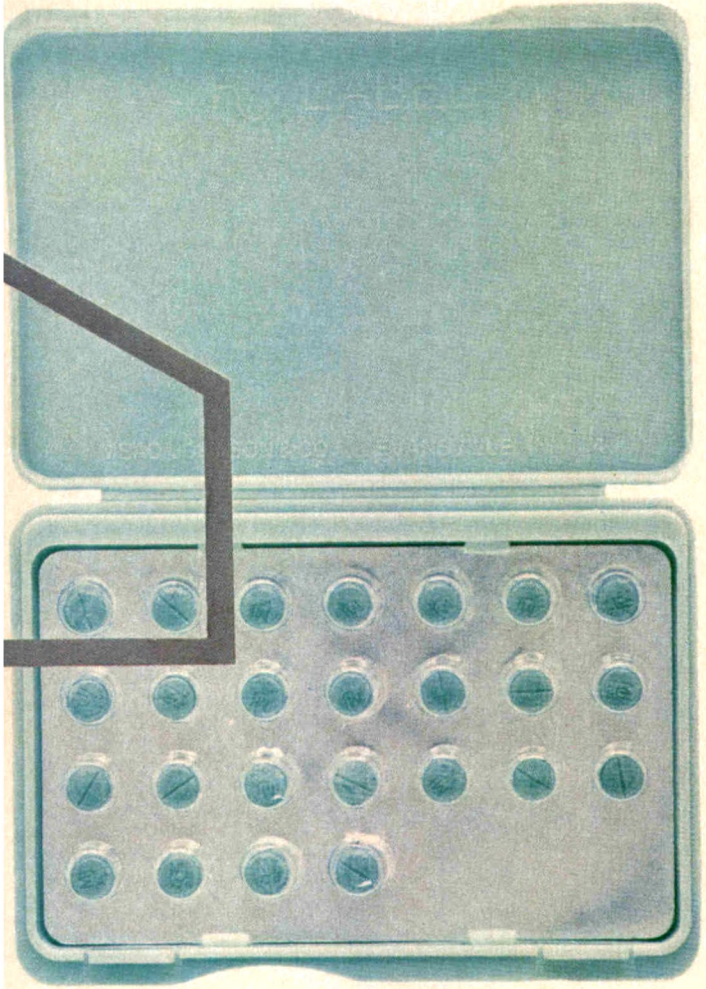


Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

THE RIGHT CHEMISTRY



THE RIGHT REPLACEMENT FOR 17β-ESTRADIOL— 17β-ESTRADIOL

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 USA MJL 5-4169

THE RIGHT REGIMEN

THE FIRST 25 DAYS OF THE MONTH— EVERY MONTH

ESTRACE is 17β-estradiol—just like the estrogen she made before menopause. Like the natural hormone, it follows a simple, well-known metabolic pathway, and it provides unsurpassed relief of postmenopausal vasomotor symptoms.

Micronized for good oral absorption, ESTRACE produces prompt, predictable serum levels of estradiol and estrone. Between cycles, ESTRACE is rapidly eliminated, providing estrogen replacement therapy that closely follows the premenopausal pattern . . . *for true cyclic therapy.*

Now it's in the ESTRACE Cycle Pak—an easy-to-carry compact, designed to deliver a starting dose of 2 mg in the preferred 25-day regimen. Cycle Paks delivering 1 mg daily are also available, if needed.

Mead Johnson LABORATORIES

For Brief Summary, please see following page.

ONLY NEW ESTRACE® (ESTRADIOL) TABLETS 1 mg and 2 mg CYCLE PAK HAS BOTH

ESTRACE® (estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

Warning

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If ESTRACE® (estradiol) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma—palliative therapy of advanced disease. *Vaginal Cream:* Atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Known or suspected cancer of the breast, except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

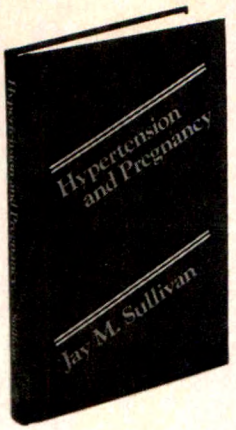
Warnings: Estrogens increase the risk of carcinoma of the endometrium (See Boxed Warning). Prescribe cautiously in women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms. A 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease has been reported in women receiving postmenopausal estrogens. There is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders or (except in treatment of malignancy) with a history of such disorders in association with estrogen use; they should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis; when estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptives should be considered a clear risk. Hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Increased blood pressure occurs with use of estrogens in the menopause, and blood pressure should be monitored, especially with high doses. Diabetic patients should be carefully observed for decreased glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases; if this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General*—A complete medical and family history should be taken prior to initiation of therapy. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination. Conditions influenced by fluid retention, such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc, may develop. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. Pathologists should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops, discontinue use while cause is investigated. Administer with caution in patients with impaired liver function, metabolic bone diseases associated with hypercalcemia, or renal insufficiency and in young patients with incomplete bone growth. The following endocrine and liver function tests may be affected by larger estrogen doses: increased sulfobromophthalein retention; increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration. *Information for the Patient*—See text of Patient Package Insert. *Pregnancy Category X*—See Contraindications and Boxed Warning. *Nursing Mothers*—Administer to nursing mothers only when clearly necessary.

The 2-mg tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, frequently those who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported: *Genitourinary system*—Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*—Tenderness, enlargement, secretion. *Gastrointestinal*—Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice. *Skin*—Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption. loss of scalp hair, hirsutism. *Eyes*—Steepening of corneal curvature; intolerance to contact lenses. *CNS*—Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*—Increase or decrease in weight, reduced carbohydrate tolerance, aggravation of porphyria, edema, changes in libido.

How Supplied: Tablets, containing 1 mg (lavender) and 2 mg (turquoise) micronized estradiol, in bottles of 100 and compacts of 25; Vaginal Cream, each gram containing 0.1 mg 17β-estradiol in a nonliquefying base containing purified water, propylene glycol, stearyl alcohol, white ceresin wax, glyceryl monostearate, hydroxypropyl methylcellulose, sodium lauryl sulfate, methylparaben, disodium edetate, and *t*-butylhydroquinone, in 1½-oz (42.5-g) tubes with calibrated plastic applicator for delivery of 1,2,3, or 4 g and in 1½-oz (42.5-g) refill tubes.



For Prescribing Information, please see physician package insert.

Important New Publications in Obstetrics and Gynecology

GREENHILL'S SURGICAL GYNECOLOGY, 5th EDITION

Editors: **Stephen L. Corson, M.D., Thomas V. Sedlacek, M.D., Jerome J. Hoffman, M.D.**

This complete study of surgical gynecology has been revised and redesigned to incorporate new procedures with many new illustrations. Written by three renowned gynecological surgeons, this text serves as a quick reference and mini-atlas, coupled with a concise, explanatory text.

1986 approx. $65.00
approx. 352 pp./approx. 148 illus.

REPRODUCTIVE SURGERY

Editors: **Alan H. DeCherney, M.D., Mary Lake Polan, M.D.**

This new book integrates the fundamentals of reproductive endocrinology and surgical correction of infertility, progressing from physiology and pre-operative evaluation through surgery and post-operative care.

1986 approx. $49.95
approx. 384 pp./119 illus.

HYPERTENSION AND PREGNANCY

By **Jay M. Sullivan, M.D.**

This book begins as a discussion of the regulation of circulation and is followed by a chapter on the circulatory adjustments caused by pregnancy. In addition, pregnancy-induced hypertension, the consequences of elevated blood pressure during pregnancy, the goals of antihypertensive therapy and the methods of antihypertensive management are presented.

1986 223 pp./39 illus. $35.00

ATLAS OF FEMALE INFERTILITY SURGERY

By **Robert B. Hunt, M.D.**

This comprehensive new atlas offers you virtually everything you need to know in order to perform infertility operations in an expert manner. Over 400 photographs present the physiology and pathology of common diseases, operations—on the uterus, fallopian tubes and ovaries, documentation by computer and video, as well as sections on hysteroscopy and laparoscopy.

1986 415 pp./457 illus. $139.95

ALL BOOKS FREE ON 30-DAY APPROVAL!

To order simply check the books listed below and mail this form or call **toll-free 800-621-9262** Monday through Friday (Continental U.S., Virgin Islands and Puerto Rico only). In IL **call collect 312-726-9746.**

Please send on 30-day approval:

____Corson: **GREENHILL'S SURGICAL GYNECOLOGY** (SG-5) . . . . . approx. $65.00(†)
____DeCherney: **REPRODUCTIVE SURGERY** (GKY-1) . . . . . approx. $49.95(†)
____Sullivan: **HYPERTENSION AND PREGNANCY** (WOP-1) $35.00
____Hunt: **ATLAS OF FEMALE INFERTILITY SURGERY** (GHU-1) $139.95

Prices quoted are in U.S. dollars. Canadian orders will be billed in Canadian funds at the approximate current exchange rate. A small additional charge will be made for postage and handling. Illinois and Tennessee residents will be billed appropriate sales tax. All prices quoted subject to change. Title marked (†) is forthcoming, please do not send cash for this book.

CURRENT DIAGNOSTIC AND THERAPEUTIC MANAGEMENT OF GYNECOLOGIC CANCER

FRIDAY & SATURDAY
OCTOBER 17-18, 1986

This program is designed for the practicing gynecologist and oncologist and will address current knowledge on gynecologic cancer required for diagnosis and treatment.

The definition, diagnosis and treatment of pre-malignant and early invasive tumors will be discussed initially (Session A). Proper understanding of the pathology of these states will enable the practicing gynecologist to initiate the safe delivery of high-quality care. This, in turn, may contribute to improved survival of these patients. This session will also define the pathophysiology and etiology of such early lesions and, therefore, should be of interest to a wide audience.

The course will also address recent therapeutic advances in selected topics of interest which are often encountered in the gynecologic practice (Session B). Controversial issues will be discussed by the participants and faculty at panel sessions.

A special session (Session C) is devoted to ovarian cancer. Extensive efforts in basic and clinical research have been devoted to this disease in the past decade. The current data and clinical applications will be presented, including topics such as tumor markers, hormonal receptors, intraperitoneal therapy, and new chemotherapeutic drugs.

COURSE DIRECTORS: E. Mark Beckman, M.D. and Uziel Beller, M.D.

TRANSACTIONS OF THE FIFTY-SECOND ANNUAL MEETING OF THE PACIFIC COAST OBSTETRICAL AND GYNECOLOGICAL SOCIETY

Your morality or mine? An inquiry into the ethics of human reproduction

Presidential address

Edward C. Hill, M.D.

San Francisco, California

There are two parts to the human dilemma.
One is the belief that the end justifies the means, . . .
the other is the betrayal of the human spirit:
the assertion of dogma that closes the mind.
Jacob Bronowski[1]
The Ascent of Man

If ethics is defined as the study of ideal conduct, then medical ethics becomes the study of ideal conduct by health care professionals: that is, whether our actions in the pursuit of our profession are right or wrong. To those of us who were graduated from medical school 40 years ago, the term "medical ethics" conjures up images of the Hippocratic oath, with its resolve to do no harm and emphasis on the responsibility of the physician as a teacher. Or perhaps it brings to mind the *Principles of Medical Ethics of the American Medical Association*, the preamble of which stresses the primary benefit of the patient but recognizes the physician's responsibility to society, to other health professionals, and to one's self. In any event, there was no formal training in moral philosophy in medical school. Whatever skill we developed in coping with ethical dilemmas came about as a result of bedside teaching in the Osler tradition. It developed from emulation of those whose value judgments we admired. However, 30 or 40 years ago such value judgments seemingly were relatively simple and straightforward. Families looked to their physicians, as well as their religious leaders, for guidance and counsel. The family physician, as an observer of the human condition in the broadest sense, was at least as well qualified as others to do so. Medical progress had not yet reached the point where technology made it possible to transplant organs, to insert man-made ones, or to sustain indefinitely a life that hung in the balance and where, indeed, even the distinction between life and death could be difficult. The progress of medical science in the past three or four decades has surpassed the wildest dreams of most of its observers and practitioners. But advancing technology has brought with it a host of new problems, and most of these problems have centered around the morality of applying or not applying the technology. Karen Quinlan, Baby Fae, Baby Doe, Barney Clark, William Schroeder, William Bartling, and the Frustaci septuplets are cases in point. Increasingly, medical decisions have come into conflict with moral standards of at least an audible section of our pluralistic society. Now the physician finds his actions being carefully and closely scrutinized by a host of people in other disciplines—sociologists, economists, psychologists, political scientists, politicians, theologians, attorneys, and philosophers. A voluminous literature on medical ethics has evolved

From the Department of Obstetrics and Gynecology, University of California, San Francisco.

Presented at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.

Reprint requests: Edward C. Hill, M.D., 350 Parnassus Ave., Suite 300, San Francisco, CA 94117.

during the past decade, with over 200 articles a month being published. Much of the rhetoric is counterproductive, "some consisting of largely ungrounded assertions . . . and others mere collections of woesome, top-of-the-head remarks by otherwise creditable scholars."[2] Moreover, the criticism doesn't always pertain to medical decisions made by physicians. Here is an item that illustrates the point. It appeared in the *Hastings Center Report*, the publication of the prestigious Institute of Society, Ethics and Life Sciences, and is entitled "The Best Little Doctors' Investment in Winnemucca":

Silvia Binder, a French woman who has operated three brothels in Winnemucca, Nevada, recently put up her business for sale. Prostitution is legal in Winnemucca, a little town of 4,000 residents 150 miles from Reno. However, according to U.S. Naturalization Service regulations, it is a "deportable occupation," and as a noncitizen Mme. Binder faced deportation for her activities. According to a UPI report (*New York Times*, December 17, 1982) a group of California doctors came up with the $2.5 million purchase price. Their background will have to be checked by the police before the license transfer is approved, and if they pass the test, their names will be made public. The investment broker who arranged the deal said that "it makes a lot of sense financially." But is it ethical? That question seems not have come up.[3]

The editor failed to say whether the ethical question was the purchase of the bordello or the publication of the physicians' names.

To be serious, though, there is a comprehensive literature in bioethics that is valid and thought-provoking, offering at least different viewpoints on issues that all of us find troubling. Physicians in general, and obstetrician-gynecologists in particular, have difficulty enough in keeping up with the scientific literature, having little opportunity to familiarize themselves with publications airing issues of medical ethics. It is my purpose to summarize an inquiry into the recent literature on this subject, especially as it applies to obstetrics and gynecology, and to try to formulate a conclusion based on that inquiry.

Certainly, medical ethics is not new, but in the past 10 years it has received a great deal of attention. Almost all medical schools have introduced formal ethics courses, most of them conducted by nonphysicians. Most hospitals now have an ethics committee with a multidisciplinary composition. A Presidential Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, appointed in 1979, recently summarized its findings.[4] With all of this activity, one gains the impression that medical morality must be different from common, everyday morality, but it is not. What makes it notable is that it deals with topics that are highly complex and emotionally charged. It involves situations to which everyone can relate in terms of his or her own health or well-being. Moreover, as one observer[5] has noted, it may be a question in which "the facts, probabilities, distinctions, risks and benefits are so involved that it is not easy to act in accord with moral rules even if you want to." To compound the problem, and the medical profession is in a large measure responsible for doing so, technology has given the impression to the public that it is capable of anything. We have created the illusion that with appropriate tests, diagnoses are not missed, and with proper treatment, cures are ensured. With the availability of pacemakers, coronary bypasses, artificial hearts, and kidney, heart-lung, and liver transplants, eternal life is attainable. If anything goes wrong, it is the fault of the physician. The media, along with a great deal of wishful thinking on the part of everyone, have fostered and nourished this illusion. It has been said[6] that physicians have all too unquestioningly accepted the burden of being healers of all the ills of mankind.

Little is said about the enormous degree of uncertainty that exists in medical practice, a fact we live with daily. We have been accused of not disclosing uncertainty for fear of losing power and control over the decision-making process or losing the confidence of the patient. A major benefit of modern medical technology is a significant reduction in the degree of uncertainty. Remember what it was like to practice without the benefit of sophisticated laboratory tests, sonography, computerized axial tomography scanners, magnetic resonance imaging, mammography, amniocentesis, laparoscopy, fetal heart monitoring, chorionic villus sampling, antibiotics, blood banks, methotrexate, and Medline searches? The quality of medical care has never been better, but the overall confidence of the public in the medical profession has never been worse. In part this is due to the existence and use of modern medical technology oftentimes as a substitute for the development of the traditional doctor-patient relationship. Technology begs to be used! There is no question in my mind that there is rampant overutilization. Another responsible factor is the fragmentation of medical care into the various specialties and subspecialties so that the patient is never treated as a "whole person." In his delightful essay entitled "The Seven Sins of Medicine," Richard Asher[7] listed overspecialization as one of the sins and related that he had seen an ophthalmologist, when asked to see a patient with retinitis pigmentosa, write in the chart, "This might be part of the Laurence-Moon-Biedl syndrome; is there any evidence of polydactyly?"

At any rate, the medical ethics debate has picked up a full head of steam, and because many of the moral issues of the day involve human reproduction, the practice of obstetrics and gynecology is right in the middle

of it. Abortion, adolescent sexuality, artificial insemination, contraception, defective newborns, genetic screening, in utero treatment, in vitro fertilization, sex preselection, and surrogate motherhood all feature prominently in current discussions. These are not just medical issues, however; they are social issues as well and thus are the concern of everyone.

Kenneth Ryan,[8] in his thoughtful Joseph Price Oration at the Third Annual Meeting of the American Gynecological and Obstetrical Society last year, pointed out the fallacy of discussing the morality of sexual attitudes and the control of human reproduction without a knowledge of the historical evolution of these aspects of human behavior. The move toward abortion reform in the State of California and the role played by some of the members of this society are vivid in the memories of many of us. The highly publicized plight of Sheri Finkbine of Arizona, the mother of four children all under the age of 7 years, who had unwittingly taken Thalidomide early in her fifth pregnancy and then was denied an abortion in this county and even in Japan, is easily recalled. Fortunately, she was able to obtain a legal abortion in Sweden, the fetus being described to her as "an abnormal growth that would never be a normal child."[9] Subsequently she had a normal fifth child. And who can forget the rubella epidemic of 1964-1965 and the seven reputable San Francisco Bay Area obstetrician-gynecologists who risked their reputations and their licenses to practice when they openly declared in a *Life* magazine article that they were interrupting pregnancies on fetal indications, a practice which at that time had no legal sanction? California led the country in recognizing the archaic nature of its old abortion law. The new law of 1967 gave legal protection to physicians who were performing so-called therapeutic abortions on fetal indication. Governor Ronald Reagan threatened to veto the bill unless specific reference to "fetal indications" was deleted. A compromise bill was passed which, in effect, allowed physicians some latitude without writing into law the concept that the embryo represents a full human person. This new law satisfied the medical profession, but no one at that time foresaw the impact of the women's rights movement and the subsequent 1973 landmark decision of the U.S. Supreme Court in *Roe v. Wade*. The court agreed, in essence, that up to the point of viability of the fetus, a woman had the right to control what was happening to her own body. The rights of the fetus were not equal until it was capable of maintaining an independent, extrauterine existence. Abortion on demand through the second trimester of pregnancy became the law of the land. In the 12 years since that time, over 16 million abortions have been performed in the United States. The number of abortions equals the number of live births in many areas of the country. But serious questions are still being asked about the morality of such a law.

The debate rages on—the pro-lifer advocates at one extreme and the pro-choice advocates at the other. The majority of the American public is somewhere in between, but the country has been polarized by this problem in a way that hasn't occurred since the slavery question almost destroyed the nation over 120 years ago. The emotional conviction the extremists bring to the abortion debate and the dogmatic positions they have taken have made a resolution of the problem impossible. Violence and terrorism have become the tractics of some. Individual physicians have entered or stayed away from the abortion arena according to their own consciences. One of the most vociferous and most visible has gone from one extreme to the other. A former director of the largest abortion clinic in the country resigned after having supervised over 60,000 abortions. In 1974 he wrote, "We must work together to create a moral climate rich enough to provide for aborition, but sensitive enough to life to accommodate a profound sense of loss."[10] He has now been completely converted and has aligned himself with the pro-life contingent, actively campaigning against abortion just as militantly as he did in 1969 when he helped organize the National Abortion Rights Action League. He says that he has seen the light, and an extremely biased videotape of an abortion pictured in real-time sonography, entitled "The Silent Scream," is his weapon. This "about face" brings to mind Arthur Koestler's comments[11] about the convert:

> To say that one had "seen the light" is a poor description of the mental rapture which only the convert knows (regardless of what faith he's been converted to). The new light seems to pour from all directions across the skull; the whole universe falls into patterns like the stray pieces of a jig-saw puzzle assembled by magic at one stroke. There is now an answer to every question, doubts and conflicts are a matter of the tortured past—a past already remote, when one had lived in dismal ignorance in the tasteless, colorless world of those who don't know. Nothing henceforth can disturb the convert's inner peace and serenity—except the occasional fear of losing faith again, losing thereby what alone makes life worth living, and falling back into the outer darkness, where there is wailing and gnashing of teeth.

The American public is deeply troubled by the abortion debate. A *Newsweek* magazine poll[12] taken this year revealed that 58% would support a ban on legalized abortion except in cases of rape, incest, and danger to the mother's life, but even more significantly, 40% have doubts about whether their position is right, regardless of whether they support or oppose it.

Kristin Luker,[13] associate professor of sociology at the University of California, San Diego, has published the

results of her own study of the abortion question—a study that she admits was conducted in order to explore her own feelings. *Abortion and the Politics of Motherhood* compares the socioeconomic structure and values of those individuals who are most active in the pro-life and the pro-choice movements. It reveals that women involved in each group, by and large, are from entirely different walks of life. The pro-choice advocates are career women who are trying to balance positions in the work force with reproduction. Those who consider homemaking and childrearing their primary goals make up a large part of those who actively condemn abortion. Each faction believes that if the other were to triumph, their own lives would have less meaning. Dr. Luker concludes that "it is not surprising that the abortion question has generated so much heat and so little light." Daniel Callahan,[14] director of the Hastings Center (Institute of Society, Ethics and the Life Sciences), says that the kindest thing one can say about the more monomaniacal supporters of either the pro-life or the pro-choice position is that they deserve each other.

One thing about abortion is certain. It is a fact of life—a reality. The morality of abortion cannot be legislated. It is, always has been, and always will be a tragic choice. As with so many judgments in medical practice, the decision involves a choice of the least bad alternative. Abortion can be morally justified provided it is done to relieve suffering and to ease the burden to the patient, her family, and to society. Our responsibility is to recognize the sovereignty of individual consciences—to help our patients consider all the ramifications of their predicament so that they can choose the course they can live with. If that choice involves termination of the pregnancy, then it should be done as early as possible, with safety, compassion, and a deep sense of loss for the life that is sacrificed.

Artificial insemination, surrogate mothering, and in vitro fertilization all have troublesome moral implications. There is little ethical concern with artificial insemination using the husband's semen (AIH). Artificial insemination with donor semen (AID) is another matter. Although it has been practiced for over 40 years, there remain questions regarding the legitimacy of the resulting offspring. A conservative estimate of 8000 babies each year result from impregnation by donated sperm. The conscientious physician involved in this type of activity has, in past, made an attempt to match the physical characteristics of the donor and the infertile husband, as well as to exercise due care and caution in selecting donors with the proper Rh type and in avoiding major genetic problems. The identity of the donor is protected, and some even mix the donor's and the husband's semen. Now, however, there are sperm banks offering frozen sperm for sale. Even do-it-yourself instructions are available for any women who desires to bear an infant—the so-called "baster babies," because in some instances insemination is carried out using a meat baster to introduce the semen into the vagina.

Of almost 400 practitioners of donor artificial insemination surveyed,[15] 80% use medical students or resident physicians almost exclusively as donors. One, in fact, had used a single donor for 50 pregnancies. This practice has caused some critics to claim that these physicians are making eugenic decisions and using what they consider to be "superior" genes for donor artificial insemination. They object that although the physician may believe that society needs more of the attributes possessed by physicians, it is unlikely that society does. Well, I say, better the attributes of doctors than those of lawyers. It doesn't seem to cross the minds of these critics that medical students and residents merely serve as a readily available and reliable source of donor semen. Moreover, in our increasingly egalitarian society, medical students represent a very broad cross section.

Some sperm banks fill over 100 orders a month, and some deal directly with the consumer. The Oakland, California, Feminist Women's Health Center has its own sperm bank and serves "all women regardless of their race, marital status, or sexual orientation." Single women, lesbians, and women with infertile partners are invited to participate. This organization estimates there are between 15,000 and 20,000 conceptions each year by donor artificial insemination and that 10% of these are in unmarried women or lesbians.

In Escondido, California, the Repository for Germinal Choice obtains and freezes sperm only from donors who meet rigid intellectual requirements. In 1982 it announced the birth of its first baby, the offspring of a woman with a high intelligence quotient and a Nobel prize–winning mathematician. Subsequently it was learned that the mother and her husband had served a prison sentence for fraud.

Aldous Huxley and George Orwell described a future world in which couples use donor artificial insemination voluntarily, using a central sperm bank supplied by carefully selected donors to increase the general intelligence quotient, or one in which donor artificial insemination is mandatory, with all marriages requiring advance approval by the "Party."

There is no question of the need for public discussion of the ethical and legal questions posed by donor artificial insemination, including its effect on marriage, on the family, and particularly on the welfare of the offspring. Should donor artificial insemination be carried out only by physicians, and if so, how can such a policy be enforced? Can one prohibit the artificial insemination of single women or lesbians on the basis that married couples make better parents? To do so

would be to discriminate because of marital status, a violation of a current legal principle. Obviously, some regulation of donor artificial insemination is necessary, and this should take the form of developing proper screening standards within the profession. Sperm banks should be held to the same standards.[16] The recent report[17] from Australia that it was "highly likely" that four women were exposed to human T cell lymphotropic virus type III (HTLV-III) from donor artificial insemination using semen from one particular donor makes this even more imperative. The California State Director of Public Health has ordered that all donors be tested for the acquired immune deficiency syndrome virus antibody. The similarity between the two acronyms, AID and AIDS, is positively eerie!

Surrogate motherhood is an outgrowth of artificial insemination. Several years ago a married woman in Dearborn, Michigan, infertile because of a hysterectomy, wanted a baby. An unmarried female friend volunteered to be impregnated by artificial insemination, using the husband's semen, and all three lived together during the subsequent pregnancy. This case was widely publicized, and the attorney who handled the case received many requests for a similar arrangement from other infertile couples. Surrogate motherhood-for-pay was the next step, and it wasn't long before a physician in Kentucky had about 100 women willing to be surrogate mothers. The fees ranged from $5000 to $10,000 each for the volunteer woman and for the attorney handling the legal arrangements. Moralists believe that surrogate motherhood represents an abuse of the lower socioeconomic class, from which most of the volunteers have been recruited. Some have looked on such contracts as baby selling. Most states have statutes prohibiting the placement of a child for adoption in return for a fee. The Michigan statute has been challenged because of the fear that it might prevent the payment of a surrogate mother. The petition has been denied, but the judgement is under appeal. The American College of Obstetricians and Gynecologists guidelines for physicians on surrogate motherhood state that there are "significant reservations about this approach to parenthood."

Nevertheless, surrogate motherhood is flourishing, and I have in my practice a young woman who is infertile because of a hysterectomy. She recently acquired an infant from a surrogate mother in Los Angeles and is very happy with the arrangement. Nevertheless, there have been some problems. In one recent case[18] a dispute arose when a microcephalic child was born and no one wanted to accept it. Eventually the surrogate mother and her husband accepted responsibility when it was learned that she had unwittingly conceived by her husband prior to being inseminated with the contracting man's semen. Suppose the surrogate mother changes her mind and decides to keep the baby. If she is married, her husband is the presumed father, and legally she could almost certainly keep the baby. If she is unmarried, there is a possibility that she could successfully sue the sperm donor for child support. This scenario has been outlined by an attorney ethicist[19] who says that the old adage "Mama's baby, papa's maybe" can be applied to the legal reaction to a surrogate mother who changes her mind. He has rather cleverly discussed the issues of contracting for a baby in terms of the Uniform Commercial Code as it might apply.[20] The code specifies that "if the goods or the tender of delivery fail in any respect to conform to the contract, the buyer may (a) reject the whole, (b) accept the whole, or (c) accept any commercial unit or units and reject the rest" (sec. 2-601). It also states that "if the seller gives no instructions within a reasonable time after notification of rejection the buyer may store the rejected goods for the seller's account or reship them to him or resell them for the seller's account" (sec. 2-604).

Louise Joy Brown, born in England on July 25, 1978, was the first known baby to result from in vitro fertilization, the result of efforts by Drs. Patrick Steptoe and Robert Edwards. Howard and Georgeanna Seegar Jones opened the first such clinic in the United States, in Norfolk, Virginia, and on December 28, 1981, Elizabeth Carr became the first baby born in this country after in vitro fertilization. There are now more than thirty such clinics in the United States, and more than 500 pregnancies have been recorded.

Paul Ramsey,[21] a theologian–medical ethicist, wrote in the *Journal of the American Medical Association* in 1972 that he considered in vitro fertilization to be "unethical medical experimentation on possible future human beings and therefore subject to absolute moral prohibition." The late Andre Hellegers,[22] of Georgetown University and director of the Kennedy Institute of Medical Ethics, thought that in vitro fertilization posed a threat to marriage and the family and, furthermore, that research in this area would lead to ethically undesirable research on late-stage fetuses.

Despite these concerns, in vitro fertilization is now firmly entrenched as a method of overcoming the infertility of women with bilateral tubal obstruction. Few now object to the use of this new technology for this purpose. Superovulation with harvesting, fertilization, and transfer of multiple ova is the technique that most clinics use to enhance the probability of a successful intrauterine pregnancy. However, a question has arisen as to whether or not it might be better to freeze the embryos for transfer in a subsequent cycle inasmuch as the drugs used for superovulation may interfere with implantation during the same cycle. It would also be more economical and would reduce the risk of multiple pregnancy. Serious ethical dilemmas have arisen from

the practice of freezing embryos for later transfer. The Rios case in Australia, in which a wealthy, infertile couple was killed in an airplane accident and left their frozen potential "heirs," illustrates the point. If only one zygote is transferred and implantation occurs, what does one do wth the fertilized eggs in the freezer? Should they be discarded? Is it appropriate to use them for experimental purposes?

The American Fertility Society guidelines state that it is ethical to experiment on human embryos fertilized in vitro—but only prior to the appearance of the primitive streak, the anlage of the neural tube, at about the fourteenth day. It allows the discarding of eggs up to that time and insists that strict rules define ahead of time the fate of frozen embryos. As of April of this year, eight babies—two in The Netherlands and six in Australia—have resulted from the transfer of thawed frozen embryos.[23] Several American clinics are trying cryopreservation techniques. One medical observer of in vitro fertilization in the United States[24] predicts that human embryos will eventually be grown in the laboratory beyond the blastocyst stage and that research activities will center on gene expression (including the role of oncogenes), chromosome segregation, cell and organ differentiation, implantation, and fetus-environment interaction. Because of the pressures to learn as much as possible about the process of human reproduction, even attempts at complete ectógenesis should not be ruled out.

The Joneses' clinic in Norfolk, Virginia, now has a waiting list of more than 8000 couples (a backlog of 16 years at the present rate) and plans to transfer about 2000 fertilized eggs this year.[25] The director of research at this clinic is the same individual who, at the National Institutes of Health, succeeded in producing normal, term pregnancies in castrated surrogate monkeys through embryo transfer and hormone replacement therapy.[26]

Let's look at what human reproductive technology has accomplished. With the advent of effective contraceptives, we had sex without babies, and with in vitro fertilization, we now have babies without sex. A possible combination of in vitro fertilization, artificial insemination with donor semen, and surrogate mothering would involve as many as five different "parents": a man and a woman to donate sperm and ova, a surrogate mother to receive the embryo, and an entirely different couple to adopt the baby. The question is, who is looking out for the interests of the baby?

One philospher[27] strikes an optimistic note, however. He believes that the traditional technique of "making babies" will remain the method of choice because "it's inexpensive, can be performed at home, takes little time, training, or skill, and is more fun."

What are the ethical problems associated with genetic counseling and prenatal diagnosis? First, there is the problem of the increase in the numbers of torts filed against physicians ostensibly for failing to inform at-risk patients of the availability of genetic screening tests. Second, there have also been claims as a result of falsely negative screening tests. Should a defective child be born, the physician may be held liable for the entire cost of raising the child. Moreover, the affected child may sue for "wrongful life." Until recently, none of the suits has been successful; however, the California Supreme Court ruled in 1982 that such a child could recover damages for medical expenses and special training. Obstetricians increasingly are finding themselves in a "catch 22" situation. The question has been raised as to whether or not a handicapped child can sue its parents for wrongful life if an abortion were refused after prenatal diagnosis of a severe malformation. How can one conclude that a handicapped life is worse than nonexistence? On the other hand, is there moral justification for intentionally bringing a severely handicapped child into the world?

Many in the medical profession operate on the assumption that the only purpose of prenatal diagnosis is to detect fetuses with major anomalies so that they can be aborted. The pro-life advocates, of course, object to prenatal diagnosis for this reason. They either ignore or are unaware of the fact that more than 95% of women who undergo prenatal testing are found to have unaffected babies and can be reassured. Thus the number of abortions is actually decreased by prenatal diagnosis. Without the knowledge and reassurance gained by negative test results, many women are not willing to take even a slightly increased risk of carrying an affected baby. Futhermore, prenatal diagnosis serves the purpose of detecting problems in the fetus that might be remedied or ameliorated during the prenatal period. Intrauterine fetal blood transfusion for erythroblastosis fetalis is, of course, the classic example, but more recently other problems, such as fetal urinary tract obstruction, have been tackled successfully. The era of intrauterine treatment of the fetus is just beginning. What about the couples who would not consider abortion no matter what anomaly might be discovered? In some clinics such an attitude might be considered grounds for refusing to carry out the tests because of the increased risk of inducing abortion. This risk should be balanced against the fact that the discovery of an affected baby would help to prepare the family, as well as the obstetrician and the pediatrician, for the birth of a compromised child.

Another ethical question raised by prenatal diagnosis is that of sex selection, that is, of intentionally aborting a fetus of an unwanted sex. Surveys have revealed that most couples who plan more than one child prefer the firstborn to be male. Firstborn children are better

achievers. A widespread practice of choosing a male baby as the first, and perhaps the only, child would reinforce sexist attitudes, to say nothing of the social consequences of an unbalanced population. On the other hand, with the existing imbalance favoring women in the comparative longevity of the sexes, such a practice might bring about a more equal distribution of men and women in the older age group. Despite these considerations, in our present society, sexism is wrong; therefore abortion for this reason is wrong.

In trying to come to some conclusion regarding medical ethics as applied to the practice of obstetrics and gynecology, I made an attempt to go back to the basics of moral philosphy and try to learn something about ethical theory. I did so after reading that some medical ethicists believe that without a serious inquiry into ethical theory, there is little point in describing or trying to resolve ethical dilemmas. The theoretical concepts encountered were those of utilitarianism prompted by John Stuart Mill, the categorical imperatives of Immanuel Kant, the doctrine of natural law as outlined by Thomas Aquinas and promoted by the Roman Catholic Church, and the determinism of Spinoza. Reading the treatises of Mill wasn't too bad, but if any of you have tried to read the translations of the original writings of Kant, you will know why I gave up in frustration and decided to accept the interpretations of contemporary philosphers. There are several excellent summaries of ethical theory now available. All these ethical theories have features that have been incorporated by various authors into a consideration of medical ethics, but each theory has shortcomings when it comes right down to a consideration of specific cases. There are purist philosphers who adhere to one theory to the exclusion of others, but even drawing on all theories poses difficulties in developing a set of universally applicable moral laws. One is left with the need for eclecticism in drawing up a series of ethical principles that one can use in daily practice. Then I remembered that one of my heroes, Albert Schweitzer, physician, theologian, philosopher, musician, and winner of the 1954 Nobel peace prize, struggled for many years to resolve philosophical questions of ethics. He said: "All that I had learned from philosophy about ethics left me in the lurch. The conceptions of the Good which it had offered were all so lifeless, so unelemental, so narrow, and so destitute of content that it was quite impossible to bring them into union with the affirmative attitude."[28] This from an individual who had spent several years of his life in the preparation of his doctoral thesis in philosphy on the works of Immanuel Kant. Well, if a physician of the caliber of Albert Schweitzer couldn't find a common thread in various ethical theories, all of which had been well developed prior to his time, how can we be expected to do it? In Schweitzer's case, he had a moment of inspiration that solved the dilemma for him. His description of that moment is illuminating. It was after Schweitzer had earned his medical degree and gone to French Equatorial Africa as a medical missionary. He wrote:

I was staying with my wife on the coast at Cape Lopez for the sake of her health—it was September 1915—when I was summoned to visit Madame Pelot, the ailing wife of a missionary, at N'Gomo, about 160 miles upstream. The only means of conveyance I could find was a small steamer, towing an overladen barge, which was on the point of starting. Except myself, there were only natives on board, but among them was Emil Ogouma, my friend from Lambaréné. Since I had been in too much of a hurry to provide myself with enough food for the journey, they let me share the contents of their cooking pot. Slowly we crept upstream, laboriously feeling—it was the dry season—for the channels between the sandbanks. Lost in thought I sat on the deck of the barge, struggling to find the elementary and universal conception of the ethical which I had not discovered in any philosphy. Sheet after sheet I covered with disconnected sentences, merely to keep myself concentrated on the problem. Late on the third day, at the very moment when, at sunset, we were making our way through a herd of hippopotamuses, there flashed through my mind, unforeseen and unsought, the phrase, "Reverence for Life." The iron door had yielded; the path in the thicket had become visible. Now I had found my way to the idea in which affirmation of the world and ethics are contained side by side.[28]

James Brabazon,[29] Schweitzer's biographer, points out the simplicity and naïveté and yet the great power of this concept—that there is a complete interdependence of all living things—a concept that is being increasingly recognized and accepted universally. As Brabazon[29] says:

Reverence for Life commands nothing. It forbids nothing. All it requires is that whatever is done should be done in full and deep awareness. Unlike creeds and codes, which provide human beings with preconstructed decisions and take away the need for choice, Reverence for Life lays on everyone the responsibility for every action.

Yet, in contemporary literature on medical ethics, little is said of Schweitzer's contribution. Perhaps it's because present-day philosphers think that his concept is too simplistic. Well, at least it was something that I could understand.

"Reverence for Life" is an idea that may be simple and naive, as some have claimed. On the other hand, it may be extremely profound. It obviously didn't mean to Schweitzer that all life should be preserved at any costs, for he recognized that where life is harmful to other life, a choice must be made. I am certain that he

would have abhorred the use of modern medical technology to artificially prolong human life at the expense of continued pain and suffering. Moreover, he was not an antivivisectionist, as "Dear Abby"[30] would have us believe, but strongly believed that laboratory animals should not be made to suffer or to be experimented on needlessly. He believed that pain-relieving medication was a necessary part of animal exploration involving pain or discomfort. If it were necessary to sacrifice a life, he thought that an awareness of the price paid should enhance the value of the life for which it was given. Schweitzer's philosophy, in just three words, eloquently expresses a doctrine that is particularly appropriate for those of us who are so intimately involved in the process of human reproduction. It may demand nothing or require nothing, but it does compel a deep and abiding respect, not only for the beginning of life, but for the middle and the end. It means that we must continue to seek after knowledge and sharpen our scientific skills. In our fascination with the science of medicine and rapidly advancing technology, we must never lose sight of the fact that we profess to care for patients. It means that we must communicate with the patient and her family, respecting the sovereignty of her desires, her beliefs, and her aims and goals. It means that we must weigh all decisions first according to patient benefit, for, in general, what's good for the individual patient is good for society. It means, also, that we must realize—and discuss openly with our patients—the uncertainties that make obstetrics and gynecology an art. Finally, it means that we must be wary of moral extremists who believe that there is one morality that fits every situation, acknowledging that only those whose medical decisions allow for individual differences are meeting the deeper demands of the ethics of our profession.[31]

Estrogen use and cardiovascular disease

Brian E. Henderson, M.D., Ronald K. Ross, M.D., Annlia Paganini-Hill, Ph.D., and Thomas M. Mack, M.D.

Los Angeles, California

In general, epidemiologic data from case-control and cohort studies have suggested that postmenopausal estrogen use confers a moderate degree of protection from coronary artery disease. The authors report reductions in all-cause mortality rates and in mortality rates for acute myocardial infarction among estrogen replacement users in comparison with never-users. It is calculated that even a small decline in the mortality rate for coronary artery disease among estrogen users would have a major impact on the overall risk/benefit ratio associated with estrogen use. (Am J Obstet Gynecol 1986;154:1181-6.)

Key words: Estrogens, postmenopausal, coronary artery disease

Cardiovascular disease is the number one cause of death in the United States, accounting for about 650,000 deaths annually (Surgeon General's Report,[1] 1979). The possible role of estrogens in modifying the occurrence of cardiovascular disease has long been controversial. Despite decades of debate, we remain so ignorant about the role of estrogens in the etiology of cardiovascular disease that recent reviews of the risks and benefits of estrogen replacement therapy have included this disease either as a hazard[2] or as a benefit[3] of such therapy, or the issue has simply been ignored.[4] There is experimental evidence that can be interpreted as supporting both viewpoints, but the available epidemiologic literature strongly supports a beneficial effect, although the magnitude of the associated protection is undetermined.

There have now been eight published case-control studies that have contributed meaningful information on the relationship between estrogen replacement therapy and cardiovascular disease, but only a few of these studies were designed specifically to evaluate this relationship[5-12] (Table I). Of the eight studies, seven have reported a reduced risk of cardiovascular disease in estrogen users, although in the earliest of these studies the risk approached unity after adjustment for other cardiovascular disease risk factors.[6] In the one other study[9] the small number of cases (n = 17), the young age of the patients (under 50 years), and their very high frequency of cigarette smoking (90%) complicated interpretation of the results.

Our case-control study of death from ischemic heart disease[5] was conducted as part of a series of case-control studies examining the risks and benefits of estrogen replacement therapy in a southern California retirement community. The 133 female residents of this community who died of cardiovascular disease over a 5-year period were compared with women of the same age who died during the same period but from causes thought to be unrelated to estrogen use and with women of the same age who were still living in the community at the time of death of the patients. Medical records were the source of information on estrogen use. With either control group used for comparison, estrogen use was associated with a substantial reduction in the risk of dying from ischemic heart disease. The relative risk with living control subjects used for comparison was 0.4 (95% confidence interval = 0.2 to 0.8); with deceased control subjects used for comparison, the relative risk was 0.6 (95% confidence interval = 0.3 to 1.0). Although information on other important cardiovascular disease risk factors was not consistently recorded, protection was conveyed to a comparable degree in women whose medical records indicated that they had other cardiovascular disease risk factors (including a history of cigarette smoking, obesity, stroke, hypertension, diabetes, angina, or a previous myocardial infarction), as in those women for whom there was no such evidence.

There have been five published cohort studies of estrogen replacement therapy and cardiovascular disease[13-17] (Table II). Two of these studies involved specific patient populations[14, 15] and showed reduced risks of ischemic heart disease in estrogen users. The three large population-based cohort studies[13, 16, 17] have given conflicting results. In the Framingham study[13] the number of observed deaths from cardiovascular disease

Bush et al.,[17] 1983	2269 white women	Fatal CHD	0.3

CHD = Coronary heart disease; MI = myocardial infarction.

in estrogen users was equal to the number of expected deaths from the same cause in the same group; however, the number of estrogen users was small. In the Walnut Creek Kaiser Permanente study, Petitti et al.[16] reported a relative risk of 1.2 for myocardial infarction among users of noncontraceptive estrogen; however, participants in this study were generally young, and only 26 cases of myocardial infarction were observed during follow-up, with nine of these cases having occurred in estrogen users.

Results from a well-designed cohort study were recently reported by Bush et al.[17] The association of estrogen use with all-cause mortality was examined in 2269 white women, aged 40 to 69 years, who had been followed up for an average of 5.6 years in the Lipid Research Clinics Program Follow-up Study. The relative risk of death was 0.4 in estrogen users in comparison with nonusers. The relative risk of fatal cardiovascular disease in estrogen users in comparison with nonusers was 0.3.

Because of the importance of clearly establishing the degree of protection from cardiovascular disease afforded by estrogen replacement therapy, we began, in 1981, a prospective study in the same retirement community in which our previous case-control research had been conducted. This study design provided the opportunity of obtaining details on potential cardiovascular disease risk modifiers, such as prior heart disease, hypertension, and cigarette smoking, as well as on dose and duration of estrogen replacement therapy.[18]

In June, 1981, a detailed health questionnaire was mailed to all permanent residents in Leisure World, Laguna Hills, a retirement community near Los Angeles, California. Residents of this community are almost entirely white, moderately affluent, and well educated; the residents' median age is 74 years, and about two thirds are women. After three mailings and follow-up telephone contact, 11,888 (62%) of the 19,209 residents returned questionnaires; 7610 of these respondents were women.

The cohort is being followed up for all hospital admissions to three hospitals serving the area (the vast majority of these admissions occur in one hospital immediately adjacent to the community) and for deaths recorded at the Orange County Health Department and the community business office. In addition, we have conducted a biannual remailing to the cohort; the first such mailing was conducted in 1983 and revealed a loss to follow-up of just 38 members of the cohort (0.4%).

As of August 31, 1984, 435 deaths had occurred among the 7610 women who returned our initial ques-

tionnaire. The age-specific and age-adjusted death rates from all causes and from acute myocardial infarction are given in Table III. There were 242 deaths in never-users of estrogen and 193 deaths in ever-users, yielding a relative risk of 0.84. This reduction in the total mortality rate among ever-users was of borderline statistical significance ($p = 0.06$). There were 56 deaths from acute myocardial infarction among never-users, in comparison with 28 deaths among ever-users. The reduction in relative risk (0.54) among ever-users of estrogen was highly significant ($p = 0.007$). The majority of deaths in both never-users and ever-users occurred in the age decades of 70 to 79 years and 80 to 89 years. A substantial degree of protection from death caused by acute myocardial infarction was observed in both of these age groups.

The expected number of deaths from all causes and from acute myocardial infarction among ever-users was calculated with the use of the age-specific mortality rates among never-users. Among ever-users, there were 229 deaths expected, an excess of 36 deaths over the number observed. A total of 54 deaths from acute myocardial infarction were expected among ever-users, in comparison with 28 observed, an excess of 26 deaths. Thus a decreased number of deaths from acute myocardial infarction accounted for nearly three fourths of the overall reduction in the mortality rate among ever-users.

Among never-users of estrogen replacement therapy, a previous history of high blood pressure and an acute myocardial infarction or angina were both associated with a higher mortality rate from acute myocardial infarction, whereas there was no clear difference in the acute myocardial infarction mortality rate between persons who have ever smoked (the majority of whom were ex-smokers) and those who have never smoked, among different groupings by Quetelet's index or by hysterectomy status. In all these categories, ever-users of estrogen had lower acute myocardial infarction mortality rates (Table IV), and in most the observed reduction in the mortality rate was substantial.

The finding of a protective effect against death from acute myocardial infarction in estrogen users is consistent with the secular changes in the mortality rate for this disease. The cardiovascular disease mortality rate has declined nearly 30% in the past 20 years.[1] The cause of this decline has been attributed both to improved medical care and to changes in life-style.[19] It is probable that multiple factors are involved, since the decline has occurred to a comparable degree in both men and women and in both whites and nonwhites, and it is doubtful that either life-style changes or access to improved health care has occurred equally in all four groups during this period. Nonetheless, a marked decline in cardiovascular disease mortality in women is consistent with the increased prevalence of estrogen use since 1960. Since men have shown a similar decrease in mortality rates, other factors associated with the risk of cardiovascular disease must have declined to a greater degree in men than in women. One factor, the

prevalence of cigarette smoking, did, in fact, decrease 26% in men but only 8% in women between the mid-1960s and mid-1970s.[1]

The finding of a reduced risk of cardiovascular disease among estrogen users is also consistent with other, but not all, related epidemiologic observations. For example, several studies[13, 20] have found an increased risk of cardiovascular disease in women undergoing an early artificial or natural menopause, strongly suggesting that ovarian function influences risk. On the other hand, an *increased* risk of vascular disease in women who use oral contraceptives is well documented. This high risk is observed over a wide range of vascular conditions, including venous thromboembolism, myocardial infarction, thrombotic stroke, hemorrhagic stroke, and subarachnoid hemorrhage.[21-24] On the basis of data from the Royal College of General Practitioners' large cohort study,[25] the risk of vascular disease, overall, was found to be increased about fourfold in oral contraceptive users in comparison with nonusers. The effect is especially strong in oral contraceptive users who smoke.[26, 27] However, recent data from this study and others[28, 29] demonstrate convincingly that the risk of arterial disease is related to the progestin rather than the estrogen component of the pill.

The biologic effects of estrogens are numerous, but the most likely mechanism to explain their protective effect on cardiovascular disease is their ability to alter lipid and lipoprotein levels. In the Lipid Research Clinics study of postmenopausal estrogen users,[30] the median serum triglyceride level was increased 26% and serum cholesterol was decreased 4%. Larger changes were observed in the lipoprotein cholesterol fractions than in the total cholesterol levels. The median high-density lipoprotein cholesterol level was 10% higher and the very low-density lipoprotein cholesterol level was 23% higher in estrogen users then in nonusers, whereas the median low-density lipoprotein cholesterol level was reduced by 11%. Other researchers have found even larger decreases in low-density lipoprotein cholesterol levels and even larger increases in high-density lipoprotein cholesterol levels in postmenopausal women treated with estrogen replacement.[31]

It is impossible to consider the role of estrogens on cardiovascular disease risk outside the context of other known or possible risks and benefits of estrogen replacement therapy. Since 1981, there have been at least 20 published studies on the relationship between estrogen replacement therapy and endometrial cancer. Nearly all these studies found a strong association between past estrogen use and development of this disease. Generally, it has been found that women using moderately high doses of estrogen for moderately long periods increase their risk of endometrial cancer by a factor comparable to that by which moderate cigarette smokers increase their risk of lung cancer.[32-34] Despite the experimental evidence and indirect epidemiologic evidence that estrogens are intimately involved in the pathogenesis of human breast cancer, the epidemiologic literature on breast cancer and estrogen replacement therapy is confusing. In the last few years there have been six population-based epidemiologic studies that have reported on this association. As a group, these studies find little or no increased risk of breast cancer with estrogen use overall, but they do suggest that long-term use carries with it perhaps a 50% increased risk of breast cancer.[35-40] On the other hand, there are now at least five case-control studies demonstrating that women who use estrogen replacement therapy substantially reduce their risk of sustaining postmenopausal fractures.[41-45] These studies suggest that fracture risk is lower with long-term estrogen use than with short-term use and that use for 5 or more years approximately halves the risk of nontraumatic osteoporotic fractures.

There are currently few available data on the effect of cyclical progestational agents given in conjunction with estrogen on each major component of the risk-

*Case fatality rate for estrogen-induced endometrial cancer estimated at 0.05.

benefit equation. It is probable that progestational agents can minimize or even negate the carcinogenic effect of estrogens on the endometrium. It has been demonstrated that 12 or 13 days of progestational therapy each month can completely eliminate adenomatous hyperplasia,[46] a probable precursor of endometrial cancer. Although progestational agents appear to have their own beneficial effects on bone resorption,[47] there is no evidence that they further enhance the effectiveness of estrogen alone. On the other hand, progestational therapy may have a negative impact on the breast cancer and cardiovascular disease components of the equation. Mitotic activity in breast epithelium reaches a peak in the luteal phase of the menstrual cycle,[48] suggesting that progesterone, when it acts in conjunction with the luteal-phase estradiol peak, may be a breast carcinogen. As noted above, the risk of vascular disease in oral contraceptive users is clearly related to the progestational component of the pill.[28, 29] Progestational agents have the opposite effect of estrogens on high-density and low-density lipoprotein cholesterol.[49] Although hydroxyprogesterones may be less hazardous than other progestogens in relation to lipid secretion and metabolism, nonetheless they appear to totally negate the reduction in low-density lipoprotein cholesterol levels and the increase in high-density lipoprotein levels afforded by unopposed estrogen therapy.[49]

Despite the multiplicity of effects associated with estrogen therapy, if the risk of cardiovascular disease is influenced by postmenopausal estrogen use, as epidemiologic data suggest, in terms of mortality rates this would be the single most important factor in the cost/benefit equation, even if the relative change in risk is small.

One can crudely compute the effects on mortality rates, through the age of 75 years, of high-dose (1.25 mg conjugated estrogen) and moderate-dose (0.625 mg conjugated estrogen) estrogen replacement therapy given at 50 years of age to 100,000 representative U.S. women. Assuming the best available measures of incidence and 5-year survival rates for the relevant diseases and the following relative risks for high- and moderate-dose estrogen replacement therapy, respectively—fractures, 0.4, 0.4; gallbladder disease, 2.0, 1.5; endometrial cancer, 7.0, 2.0; breast cancer, 1.5, 1.1; and cardiovascular disease, 1.0, 1.0—one would expect high-dose therapy to produce a net *increase* in deaths of about 6% and moderate-dose therapy to produce a net *decrease* in deaths of about 2% (Table V).

If cardiovascular disease risk was reduced by 50%, the net decrease in the mortality rate would be in excess of 33% and 41% with high- and moderate-dose therapy, respectively (Table VI). These calculations stress the importance of determining with certainty any dose-response relationship between estrogen use and cardiovascular disease. Even in a weak dose-response relationship, the net mortality benefit to be derived from high-dose therapy would converge with that to be derived from low-dose therapy. A stronger dose-response relationship might favor high-dose therapy as a means of reducing mortality rates for estrogen-related diseases.

All these projections are crude and depend on a variety of assumptions. Nonetheless, these calculations suggest that even minor relative changes in the risk of cardiovascular disease following estrogen use can have a major impact on the overall risk/benefit equation. Just as it is important for clinicians to consider the possible effects of estrogen therapy on the entirety of the risk/benefit equation, it is also important that epidemiologists continue to refine these calculations through research aimed at measuring the effects of long-term low-dose versus high-dose therapy on the risk from cardiovascular disease, assessing the effects of combined estrogen-progestogen therapy on risk and clarifying the interactions between the effects of estrogen replacement therapy and the effects of known risk predictors of cardiovascular disease.

Fetal injury prior to labor: Does it happen?

Richard H. Paul, M.D., M. Lynn Yonekura, M.D., Cathy Jo Cantrell, M.D., Susan Turkel, M.D., Zdena Pavlova, M.D., and Louise Sipos, R.N., M.Ed.

Los Angeles, California

Major advances have been made in the identification and prevention of perinatal factors that lead to long-term handicap or neurologic deficits. When the infant or child exhibits a major handicap, secrutiny of the pregnancy management often occurs in an attempt to define the causal factors. The medical goal of this inquiry is to prevent injuries and, when possible, to eliminate these factors. In the litiginous sense, any deviation from optimal, ideal care or any unusual observations, such as unusual or atypical fetal heart rate patterns, are often causally linked to the adverse outcome. There are at least four categories of major fetal injury that probably occur prior to labor. An awareness of, and a diligent search for, details will no doubt clarify the legitimate origins of many so-called birth injuries. Hence the common tendency to fixate on minor deviations and/or deficiencies of labor and delivery management as causing catastrophic injuries will be successfully challenged. (Am J Ostet Gynecol 1986;154:1187-93.)

Key words: Birth injury, fetal heart rate patterns, perinatal asphyxia

The problem of perinatal injury and compromised long-term outcome is understandably a topic of major concern and the focus of much current attention. Although many strides have been made in reducing the incidence of neonatal birth injuries, there is increasing concern over the rising use of cesarean section to achieve this benefit. Any long-term outcome that is less than perfect is likely to raise questions regarding the adequacy of pregnancy management, with particular emphasis focused on the labor and delivery process. Often, unrealistic public expectations, coupled with the current litiginous attitude, provoke critical scrutiny of compromised outcome that a few years ago would have been accepted as a result of the natural, but imperfect, reproductive process.

When a child suffers a major handicap or neurologic deficit, such as cerebral palsy, a process of inquiry should be initiated. There is a medical obligation to identify causal factors, with the goal being to minimize or eliminate such factors. Thus genetic assessment, metabolic evaluation, and scrutiny of antepartum events are often undertaken but are rarely definitive. Final focus then falls on the events of labor, delivery, and the newborn period. This detailed inquiry, unfortunately, often occurs in the form of medicolegal confrontation, rather than in an objective scientific investigation. The adversarial nature of this confrontation is charged with emotion and reflects biases that are oftentimes devoid of a truth-seeking, objective process.

Presented at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.

Reprint requests: Dr. Richard H. Paul, Women's Hospital, Room 5K40, 1240 North Mission Road, Los Angeles, CA 90033.

Currently the major contributor to adverse outcome is premature birth. Advances in neonatal care have dramatically increased survivorship of very low birth weight infants. However, such survivors exhibit a high incidence of morbidity, such as cerebral palsy, as evidenced by the fact that the incidence of cerebral palsy has not declined in recent years.[1] Thus any evaluation of compromised newborn-infant outcome must necessarily isolate infants with low birth weight from the appropriately grown term infants. Although similar disorders may occur in both groups, the process of obstetric intervention may be dramatically different for fetuses judged to be preterm or frankly immature. Furthermore, the expectations for the preterm infant and for infants exhibiting growth disorders and/or anomalies will be less than those expected for term-size infants.

The occurrence of fetal asphyxia and its ability to cause fetal death during labor has been well documented. Older reports in the literature attempted to define various time frames of pregnancy and their relationship to abnormal fetal outcome. Such studies necessarily antedated such technologic advances as fetal monitoring, ultrasonic diagnosis, and the newborn intensive care routinely available to such patients today. Moreover, such studies described group characteristics but could not provide individualized case assessment. Although peripartal asphyxia is an accepted cause of neurologic injury, the majority of such disorders are believed to have their origins apart from peripartal events.[2]

Labor management and, in particular, the evaluation

of fetal condition during the hours of labor are viewed with suspicion in the presence of known or documented neonatal compromise. Such evaluation is not unreasonable in view of the increased incidence of death and morbidity during this relatively short period. Within such a context, charted information is of particular importance, and the fetal heart rate (FHR) data obtained with the use of electronic fetal monitoring have become the primary commentary regarding fetal status. FHR patterns influence decisions affecting both the antepartum and the intrapartum management of pregnant patients. The primary benefit of FHR assessment is the correlation between patterns judged to be "normal" and subsequent favorable, or uncompromised, neonatal outcome. The observaton of what is judged to be other than normal lacks such strong prognostic value. Much of the criticism relating to FHR monitoring focuses on the lack of specificity of abnormal patterns, which, in turn, has often led to "unnecessary" intervention. On the other hand, when one is faced with an adverse outcome, particular attention if focused on FHR patterns, especially since they are thought to reflect fetal compromise. Patterns such as late deceleration, when present over the time-course of hours, are known to be associated with acidosis, depressed neonates, and neonatal morbidity. When such events have preceded a birth and are coupled with the observation of newborn encephalopathy—that is, seizures—it is reasonable to assume that such antecedent factors may have played a role in subsequent neurologic deficits.[3, 4]

Under other circumstances, the FHR tracing does not demonstrate a pattern recognized as being associated with abnormal outcome. The most notable examples of this type occur in the dying fetus or the fetus subsequently found to exhibit major congenital anomalies incompatible with life.[5] In a number of circumstances we have encountered nonspecific FHR findings that fail to portend severe fetal acidosis or severe compromise encountered in the neonate who was anticipated to be born "normal."[6]

The question then arises: Can "abnormal" FHR patterns observed during labor result from or indicate an injury that preceded labor? The documentation of such a fetal injury depends on the identification of a lesion that chronologically must have preceded labor. The majority of such lesions have been diagnosed at the time of postmortem examination of antepartum stillborn infants and thus preclude intrapartum observation. Neonatal deaths and their respective postmortem findings are often confounded by complications that these neonates encountered in the nursery. Fortunately the diagnostic advances of computerized tomography and of ultrasonic scanning in neonates during the first hours of life have provided new insights into antenatal injuries. Lesions can be diagnosed and dated as having occurred before labor, thus exonerating the labor process as the probable causal factor when an adverse outcome is confronted.[7] Critical evaluation of intrapartum events, including FHR, are of major importance in such cases.

The recent medical literature offers evidence that there are four major categories of fetal injury that may be documented as having occurred prior to the onset of labor or delivery[8-12]: (1) intracranial hemorrhage, (2) myocardial infarction, (3) sepsis and congenital pneumonia, and (4) meconium aspiration.

Unfortunately, little information exists relevant to the intrapartum FHR findings that are unequivocally associated with fetal injuries documentable as having occurred prior to labor. Herein, we will provide examples of intrapartum FHR tracings associated with injuries that probably antedated the labor process in term infants with appropriate growth for gestational age.

Fetal injuries

Intracranial hemorrhage. Demonstration that an intracranial hemorrhage occurred during fetal life prior to labor can be made by two specific means. First, demonstration of gliosis in the brain of stillborn infants documents the chronicity of intracranial injury and hemorrhage and its necessary occurrence prior to labor.[8] Second, the demonstration of liquefication or a porencephalic cyst in the fetus or in the infant during the early newborn period provides documentation. This pathologic residual of infarction, or intracranial hemorrhage, requires a minimum of 7 days to evolve. The importance of early identification of this lesion is self-evident and may lead to a careful evaluation of the FHR characteristics associated with this chronic lesion. A recent report[11] has described the initial "normal," followed by abnormal, FHR findings associated with a major maternal complication and apparent fetal decerebration. The subsequent death and autopsy findings in this infant confirmed the timing when the insult occurred. Immediately after decerebration, the fetus demonstrated persistent lack of variability, and the intrapartum tracing showed minimal FHR variability and an absence of late decelerations.[11]

Myocardial infarction. The occurrence of myocardial infarction in the perinatal period is well known.[12] Postmortem studies during a recent 42-month period at our institution have demonstrated the occurrence of perinatal myocardial infarction in 35 cases (Turkel, S., personal communication, 1985). Findings consistent with infarction were found in 18 cases ending in five stillbirths and the deaths of 13 neonates within less than 24 hours of age. The minimal time required for the development of typical histologic findings of myocardial infarction is in excess of 24 hours. Hence these injuries

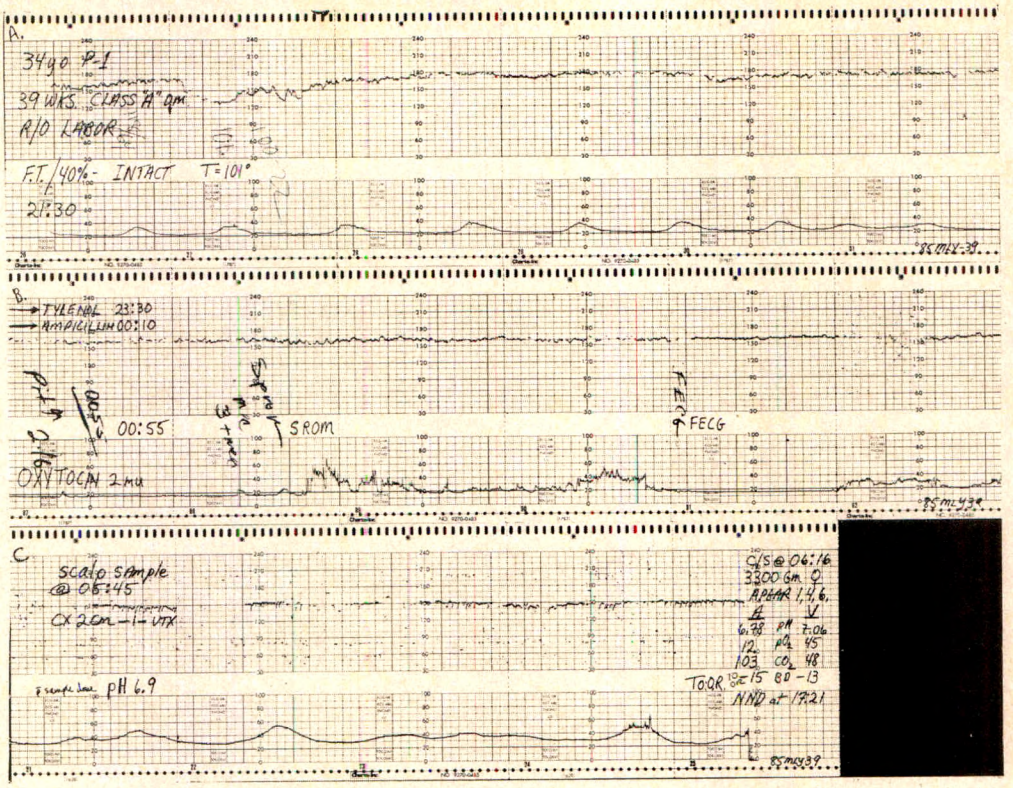

Fig. 1. Intrapartum FHR uterine activity findings associated with a fetus having intrauterine sepsis. Chronologic times may be noted in the left-hand portion of each panel.

probably occurred prior to the labor process. Five such infants weighed over 3000 gm, and five were judged small for gestational age. Unfortunately, we have been unable to identify (or retrieve) pathognomonic FHR tracings in term-size infants suffering infarctions.

Congenital infection. Sepsis in the term neonate is usually successfully treated with minimal long-term compromise. The occurrence of an early neonatal death after which a necrotizing pneumonitis was demonstrated at autopsy implies a fetal disease process of several days' duration.[10] The following case example illustrates such a case and the associated findings.

The patient was a 34-year-old woman, gravida 2, para 1, admitted at 39 weeks in early labor and with a temperature of 101° F. Physical examination demonstrated intact membranes, positive fetal movement by observation, and fingertip cervical dilation with 40% effacement, with a vertex presentation at a −3 station. The remainder of the physical examination was noncontributory, other than the abdominal examination, in which fetal weight was estimated at 3600 gm. Urinalysis and laboratory tests failed to identify the source of fever. Portions of the intrapartum FHR tracing of this patient are presented in Fig. 1. An antipyretic agent was administered, as noted in Fig. 1, *B*, to reduce the maternal fever. Spontaneous rupture of the membranes occurred approximately 2½ hours following admission and revealed thick meconium, with gram-negative bacteria demonstrated by microscopic examination. The diagnosis of amnionitis was then made and ampicillin and gentamicin therapy initiated.

Six hours after the woman's admission and after 5 hours of oxytocin administration, the cervix had become completely effaced, 2 cm dilated, with the vertex at a −1 station. Because of persistent fetal tachycardia and decreased variability, a fetal scalp sample was obtained and revealed marked fetal acidosis (Fig. 1, *C*). A cesarean section was expeditiously performed and resulted in the delivery of a depressed 3300 gm female infant. The Apgar scores were 1, 4, and 6 at 1, 5, and 10 minutes, respectively. The cord blood gas results are presented in the lower right portion of Fig. 1, *C*. The FHR findings revealed a baseline rate in excess of 160 bpm and failed to demonstrate definitive deceleration patterns throughout the course of labor. There was minimal beat-to-beat variability, as demonstrated in Fig. 1, *B*, and accelerations were not documented at any time during the 8½ hours of observed tracing. Newborn evaluation revealed a limp, cyanotic infant who had meconium suctioned from below the vocal cords twice. Resuscitative efforts were difficult. The baby could never be properly ventilated and died at 11 hours of age. Autopsy findings demonstrated necrotizing pneumonia, renal necrosis, and necrosis in additional

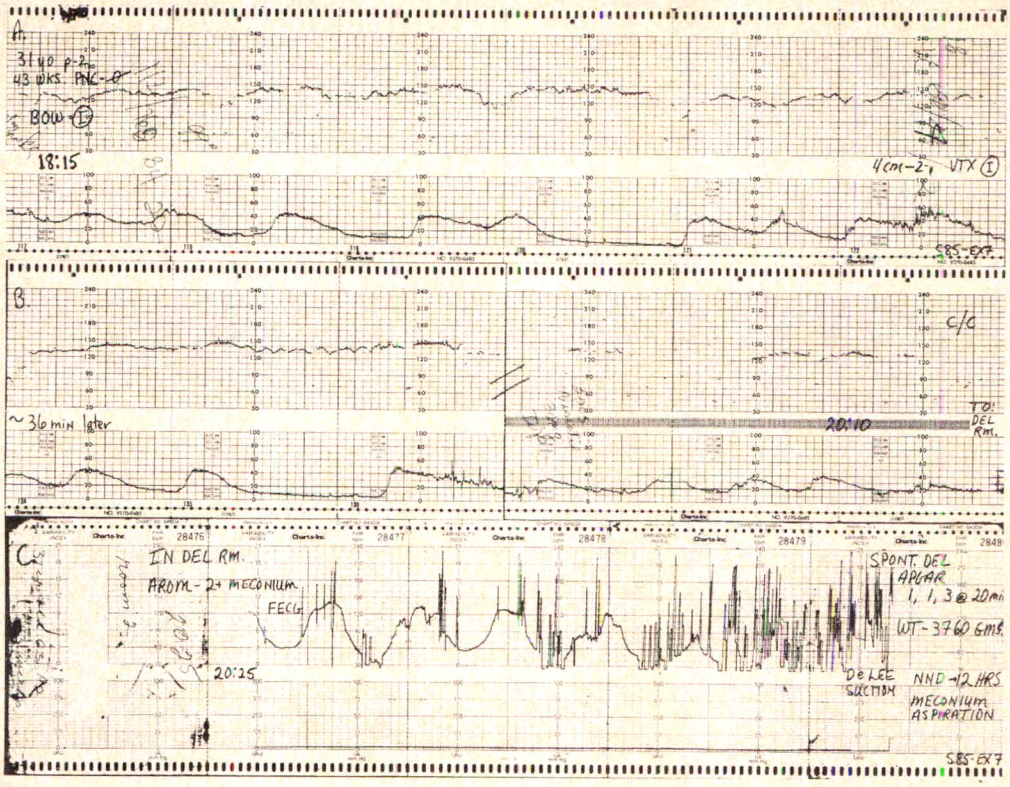

Fig. 2. The FHR uterine activity findings in a fetus that had experienced in utero aspiration of meconium. The time frame of occurrence may be noted in each panel, and the terminal direct fetal heart rate is presented in the bottom panel *(C)*.

organs. *Listeria monocytogenes* was cultured from both newborn and autopsy specimens. The mother's postoperative course was uncomplicated.

Meconium aspiration. The occurrence of meconium aspiration is a major cause of morbidity in the otherwise "normal" term-size neonate. This complication occurs more commonly in postdates pregnancies. The occurrence of meconium aspiration in utero preceding the onset of labor has been previously documented.[13] Histologic observation of macrophages containing meconium particles, in the lung, implies 24 hours or more tissue exposure to meconium. Likewise, the association of a baseline FHR is excess of 150 bpm, minimal variability, and unanticipated severe fetal acidosis and neonatal morbidity has been reported. In such cases the FHR patterns often lack episodes of acceleration or dramatic deceleration.[6] The following case illustrates the findings associated with probable meconium aspiration in utero.

The patient was a 31-year-old woman, gravida 3, para 2, who presented at 43 weeks' gestation having received no prenatal care. Physical examination performed on admission revealed a temperature of 99° F, with cervical examination showing 30% effacement, 4 cm dilation, and intact membranes with the vertex at a −2 station. FHR tracing was obtained with the use of external methods in Fig. 2, *A* and *B*. Total time of observed labor was <2 hours, as noted at the end of the Fig. 2, *B*, when the cervix was completely dilated and the patient was taken to the delivery room. When artificial rupture of the membranes revealed meconium, a fetal electrode was applied and demonstrated a markedly pathologic FHR pattern. Ten minutes later, as seen in Fig. 2, *C*, the patient was delivered of a 3760 gm infant with Apgar scores of 1, 1, and 3 at 1, 5, and 20 minutes, respectively. The fetus had undergone DeLee suctioning while on the perineum and was promptly intubated and vigorously resuscitated. In the neonatal intensive care unit a chest x-ray film revealed bilateral infiltrates consistent with meconium aspiration. The infant remained intubated and was mechanically ventilated but died at 12 hours of age. Postmortem examination of the lungs revealed extensive meconium aspiration, which was confirmed by histologic examination. In addition, acute funisitis was diagnosed, and numerous macrophages were noted in the sections from lung tissues. Perinatal asphyxia and extensive meconium aspiration were listed as the cause of death.

Comment

Currently there is unequivocal evidence that fetal injury can occur prior to the labor process. We present

intrapartum FHR tracings from selected examples of appropriately grown term neonates who apparently suffered an antepartum fetal injury. The intrapartum FHR findings often shared in common are a lack of FHR accelerations, an elevated baseline rate, decreased variability, and an atypical response or pattern lacking definitive decelerations. When the clinician encounters such findings in early labor, suspicion regarding fetal well-being should be raised.

Although these FHR findings cannot be looked on as pathognomonic of a fetal injury prior to the onset of labor and delivery, they should raise one's level of suspicion. As exemplified in our first case presentation, the occurrence of maternal fever confounds these particular observations. In several studies, intrapartum FHR tachycardia has been significantly associated with an increased risk of neonatal respiratory distress syndrome, asphyxia, and meconium aspiration.[14, 15]

The postterm infant who demonstrates the triad findings of an elevated baseline FHR, decreased variability, and meconium-stained amniotic fluid presents a unique problem. Historically, these fetuses have been noted to have increased morbidity and, often, to have FHR patterns that do not fit expected findings associated with fetal distress. Herein, we have presented a case with unusual and atypical FHR findings complicated by meconium aspiration and subsequent neonatal death. Meconium aspiration was documented at postmortem examination, and microscopic evidence suggested that aspiration had indeed occurred prior to the labor process.

In summary, we suggest that the observation of FHR patterns described in this report at the onset of labor should raise the clinician's level of suspicion that the fetus may have sustained a prelabor injury. This is particularly true if one has previously observed normal FHR or ultrasonic findings in an otherwise uncomplicated pregnancy. Thus the transition from normal to abnormal suggests that an adverse event has occurred in the fetus.

It is hoped that these observations and concepts will lead to a heightened awareness on the part of the clinicians in the search for FHR patterns that may indicate fetal injury prior to the labor process. To this end, careful antepartum, as well as intrapartum, observations are mandatory. Likewise, definitive neonatal evaluations, including creatine phosphokinase isoenzyme measurements, ultrasonic examination of the fetal head and/or heart, and other diagnostic procedures, must be promptly performed. Finally, should death occur, definitive evaluation for possible lesions and/or histologic evidence that documents the occurrence of an insult prior to labor, coupled with a detailed record of the labor process, including the FHR tracing, will no doubt clarify the probable time of occurrence in many abnormal outcomes. It is thus probable that the automatic assignment of blame to the labor and delivery process will be successfully challanged.

Discussion

Dr. Peter Roberts, Portland, Oregon. Dr. Paul and his associates have written an interesting and informative paper. Until recently, almost all occurrences of brain damage, meconium aspiration, and neonatal sepsis have been attributed to intrapartum events. Thus, if there has been any serious central nervous system or pulmonary damage in a term newborn with appropriate growth for gestational age, its occurrence has been laid to the time of labor. The burden of proof for any injury has therefore been transferred to the obstetrician, and he must defend his labor management.

This article (along with those of other authors, notably Niswander and Manning) proposes, in some instances, the occurrence of fetal damage prior to the onset of labor. This may give some medicolegal relief. However, as pointed out by Dr. Paul, our real challenge is in continuing our search for the cause of these injuries so as to minimize and/or eliminate them. Until this is accomplished, we cannot be happy (and rest assured that the attorneys won't be, either).

In reviewing the well-documented cases of prelabor pulmonary sepsis and meconium aspiration, Dr. Paul has pointed out a clear and present danger signal—namely, the triad of thick meconium, elevated baseline FHR, and the lack of beat-to-beat variability. When this triad occurs in a term or postterm fetus, immediate delivery is mandatory, so that treatment can begin and further damage can be avoided.

Before asking Dr. Paul two questions, I wish to make a comment as a practicing obstetrician. Until accurate methods are available to precisely diagnose prelabor insults, every effort must be made to prevent any damage at the time of labor and delivery. By doing so, we will most importantly prevent further morbidity of the newborn—and at the same time, if any injury is present, there will be no doubt that the injury did not happen during labor.

I have two questions. First, current teaching has been that in the case of term infants with appropriate growth for gestational age, meconium aspiration occurs as the result of a vigorous respiratory effort and that efforts of that magnitude do not occur prior to labor and/or delivery. What mechanism do you believe causes aspiration before labor? Second, in the case of antepartum brain damage, do you foresee a procedure and or a protocol for the prelabor diagnosis of fetal neurologic damage?

Dr. Theodore Loring, Eureka, California. The presentation by Dr. Paul is timely and of great importance to our specialty at the present time. We are all aware of the problem of neurologic deficits in the newborn and its impact on malpractice premiums for obstetricians.

During the past 3 years I have served on a Nationwide Neurological Deficit in the Newborn Committee with representatives from the larger physician-owned malpractice insurance companies. This study is sponsored by the Physicians Insurance Association of America. To date we have studied about 450 cases of "brain-damaged infants" and have found the problem to be astronomical, representing about $2 billion dollars in reserves. Last May, at a Physicians Insurance Association of America meeting, Dr. Sanders, a pathologist at Michigan State University, presented a glimmer of hope in this problem. His studies of placentas of newborn infants born with neurologic defects revealed a condition he calls endovasculitis of the placenta. He believes that this is a long-standing placental change that possibly accounts for the neurologic damage. Since his articles have all been in the pathology journals, most obstetricians are probably not aware of endovasculitis of the placenta. I wonder, Dr. Paul, whether you have any information on, or opinion of, Dr. Sanders' work?

I urge all of you who are delivering babies to save the placentas of all babies with a low Apgar score, as well as the monitor strips. Someday that saved placenta might save you in court.

Dr. Robert Goodlin, Denver, Colorado. I recently moved to the University Hospital in Denver, and one of the things I was looking forward to was that babies there do not die from meconium aspiration. However, within a few months, there was a case that was managed ideally, for as soon as thick meconium was noted, and with a very low scalp pH value, the patient had an immediate cesarean section. There was no meconium below the cord, and the infant had been aspirated with the DeLee apparatus. Unfortunately, the infant died of meconium aspiration, which apparently was the first such case in 10 years. I just want to point out that even the well-known system, as used in Denver, is not without the rare failure, especially if the meconium aspiration occurs before the onset of labor.

There's an interesting paper in the *Australian and New Zealand Journal of Obstetrics and Gynecology*, entitled "The Battered Fetus." The author reports on a series of women from western Samoa who were delivered of fetuses with intracranial hemorrhage, and there was no history of trauma or anything else to explain the lesion. Whenever we're attempting to defend the occurrence of these cases, remember that the battered fetuses are fairly well established in the literature.

Dr. Thomas Moyers, San Diego, California. Speaking as a practicing obstetrician and one actively involved in caring for high-risk pregnancies, I believe that this study represents an especially important direction for current and future investigation. Knowledge of the timing of the insult that results in later evidence of fetal damage, or poor outcome of pregnancy, is an essential element in defending liability claims. More important, such knowledge may lead to changes in the management of pregnancy during both the prenatal and the intrapartum period, thus improving outcome. The availability of this kind of information in the obstetric literature is important for both reasons.

Dr. Julian Parer, San Francisco, California. I believe that this work is extremely important, in agreement with the other commentators. For some time now, we've been told that most cerebral palsy is not due to intrapartum asphyxia but, rather, to antepartum neonatal or infant events. My question is, Do you have some quantification of how much of this injury occurs before labor? That is, what percentage of damage evident at birth is due to relatively remote antepartum incidents?

Dr. Paul (Closing). I'd like to thank the discussants, particularly Dr. Roberts, and try to answer the questions. The first question was, What is the mechanism responsible for meconium aspiration prior to labor? I can't definitively tell you what causes this, but it is probably some type of fetal distress factor. It is speculation

to say that the baby had a cord accident or some other event, such as a maternal disorder, that stressed the baby. Whatever the cause, the baby probably undergoes a series of gasping efforts that result in the meconium's being aspirated into the lungs.

The second question, I think, regarded the development of a standard protocol to investigate such cases. We have no specific protocol, but when there is a high level of suspicion, we evaluate suspect cases. The suspect high-risk infants are the babies who are dysmature or inappropriately grown, and they're apparently most vulnerable to problems. Dr. Greggory DeVore is working in the area of fetal cardiac function. We see a repetitive pattern of cardiac dysfunction in the fetus when growth is impaired. The right side of the heart apparently begins to become dysfunctional, and then the left side is similarly affected. In the process, a number of such patients develop oligohydramnios. These fetuses are vulnerable to the stress of labor and are probably the ones who incur myocardial infarction prior to the actual birth. Measuring isoenzymes in the cord blood of such babies then becomes very important. This is a group we're very interested in exploring. Most babies with right-sided dilation in fetal life adapt promptly, as soon as they're born. At birth the left side begins to assist the circulation. The babies may appear normal in the nursery, and yet they may have had an injury. No one knows what the long-term outcome of such findings are.

Dr. Loring asked about placental endovasculitis and Dr. Sanders' work. I have no comment in reply. I'd only make the comment that the role of infection is something that we've underestimated. The two cases I've presented, both with intact membranes on entry to the hospital, had evidence of infection at necropsy. One patient had *Listeria* infection, and the other had funisitis without systemic sepsis. There is an apparent infectious process that I think we have not paid enough attention to in the past.

Dr. Goodlin commented about a recent case of in utero meconium aspiration in Denver. I'm glad they finally have had the case.

The early reports from Denver about the prevention of such problems prompted Frank Manning to describe in utero aspiration from our service. With our volume, we see the exceptions, and we saw such a case promptly. I guess their low delivery volume finally produced such a case.

I appreciated Dr. Moyers' comment. Dr. Parer, I can't tell how many injuries occur prior to, as opposed to during, labor. We're just trying to document case-by-case observations. I would say that the majority of injuries we're talking about occur prior to labor and delivery. They're often developmental or products of some dysfunctional growth problem. You must obviously separate out babies that are growth retarded or preterm from the term infants in such estimations. I'd say that most of these injuries probably occur prior to labor.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Ultrasonographic evidence of uterine malignancy in the postmenopausal uterus

Charles B. Chambers, M.D., and Joseph S. Unis, M.D.

Pomona, California

The sonographically enlarged uterine cavity in the postmenopausal woman has been described as indicative of uterine malignancy. In this study, in 10 of 15 cases of proven uterine malignancy with prior pelvic sonographic studies there was evidence predicting the diagnosis. In 10 of 12 cases with positive sonographic findings, uterine malignancy was found at operation. This reveals a 67% rate of success as to the value of negative sonographic findings and an 83% rate of success with positive findings. Pelvic sonography is not a screening test for uterine malignancy, but if positive findings are present, surgical investigation is indicated. (Am J Obstet Gynecol 1986;154:1194-9.)

Key words: Sonography, uterine malignancy, menopause

Since the beginning of gynecologic ultrasonography, various reports have appeared describing the sonographic appearance of the uterus and endometrial cavity in the normal uterus[1] and in the pathologic nonpregnant uterus.[2] The reported findings in the postmenopausal uterus indicative of endometrial adenocarcinoma have been the fluid-filled, obstructed uterus,[3, 4] the enlarged uterine cavity,[5] the enlarged uterus,[5, 6] and the lobular uterus with a mixed echo pattern.[6] The latter finding is reported as being found in Stage III and Stage IV disease. This paper reports on the sonographic findings in 15 patients with proven adenocarcinoma of the endometrium or uterine sarcoma who had prior pelvic sonograms. In 10 of these cases (66.7%) there were findings suggesting malignancy, whereas in the remaining five cases the reports were noncontributory. Also included in the report is a prospective study of 12 cases (the 10 mentioned above plus two other cases) in which there were sonographic indications of malignancy. The purpose of this study is

From the Departments of Obstetrics and Gynecology and Radiology, Pomona Valley Community Hospital.

Presented at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.

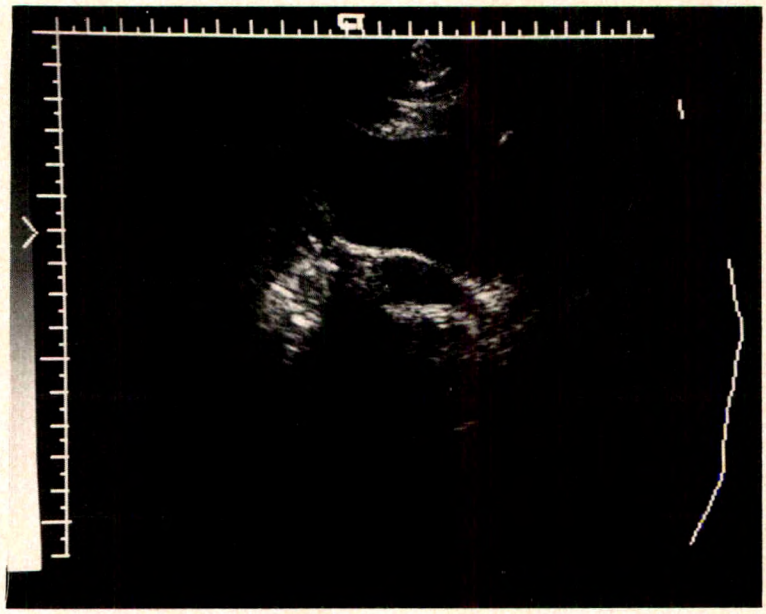

Fig. 1. Longitudinal sonogram of a normal postmenopausal uterus with uterine cavity not visible.

Table I. Preoperative sonographic findings in 15 patients with endometrial adenocarcinoma or uterine sarcoma

Patient No.	*Age (yr)*	*Sonographic findings*	*Findings at curettage or hysterectomy*
1	63	Markedly prominent endometrial echoes; uterus not enlarged	Well-differentiated endometrial adenocarcinoma with minimal myometrial invasion
2	63	Prominent endometrial echoes; uterus slightly enlarged	Well differentiated endometrial adenocarcinoma with less than one-third myometrial invasion
3	69	Enlarged uterus with diminished sound transmission or increased acoustic impedance; uterus appears homogenously involved	Curettage only; uterus 6 × 10 cm sounded to 6 cm; moderate amount necrotic tissue; poorly differentiated adenocarcinoma endometrium
4	61	Uterus diffusely enlarged with dense central endometrial echoes	Adenocarcinoma endometrium well differentiated with one-third myometrial invasion
5	80	Uterus enlarged; variable echogenicity in region of central canal	Adenocarcinoma endometrium, tumor mass measures 4.5 cm; extension to one-third myometrium
6	61	Large cavity with prominent echoes	Polypoid mass 9 × 8.5 × 5.5 cm; mixed mesodermal tumor omental metastases
7	53	Bulbous enlargement of endocervical area and proximal uterine body with increased echogenicity	Adenocarcinoma endometrium involving the lower portion of the uterine cavity and entire endocervical region
8	65	Marked increase in echogenicity of the central endometrial echo, which is also wider	Endometrial polyp 3 × 2.5 cm; well-differentiated adenocarcinoma endometrium with no myometrial invasion
9	66	Irregularly enlarged uterus with diffuse variable echogenicity	Rhabdomyosarcoma
10	75	Cavity too large for patient's age	Adenocarcinoma endometrium with cervical extension
11	53	Right adnexal mass 6 × 8 cm; left adnexal mass 2 cm; no mention of uterine size or cavity	Mucinous cystadenocarcinoma right ovary; serous cystadenoma left ovary; small superficial focus of adenocarcinoma endometrium
12	69	Uterus normal size and configuration	Multiple site papillary adenocarcinoma endometrium with one-third myometrial invasion
13	63	Uterus normal size, shape, and position	Adenocarcinoma endometrium Stage III; 4.5 cm cavity; large amount necrotic tissue
14	75	Uterus moderately enlarged and demonstrates calcification compatible with fibroids; cavity not mentioned	Adenocarcinoma endometrium filling cavity to wall of uterus with perforation; benign leiomyomata
15	55	Normal uterus with small cervical fibroid; uterine cavity not apparent	2 cm cervical leiomyoma; no cavity enlargement; plaquelike well-differentiated superficial adenocarcinoma endometrium

to evaluate this procedure by examination of these prospective and retrospective series.

Material, methods and results

Between January, 1980, and July 1, 1985, 101 patients with adenocarcinoma of the endometrium or uterine sarcoma were treated at Pomona Valley Community Hospital. Of these, 15 (14.4%) had pretreatment sonograms (Table I). During the same period the radiology department reported on 12 cases with sonographic findings suspicious for uterine malignancy (Table II). Sonographic scans were obtained on commercially available gray-scale units with 2.25 or 3.5 MHz transducers.

Comment

The postmenopausal uterus has been described as having an upper-limits anterior-posterior diameter of

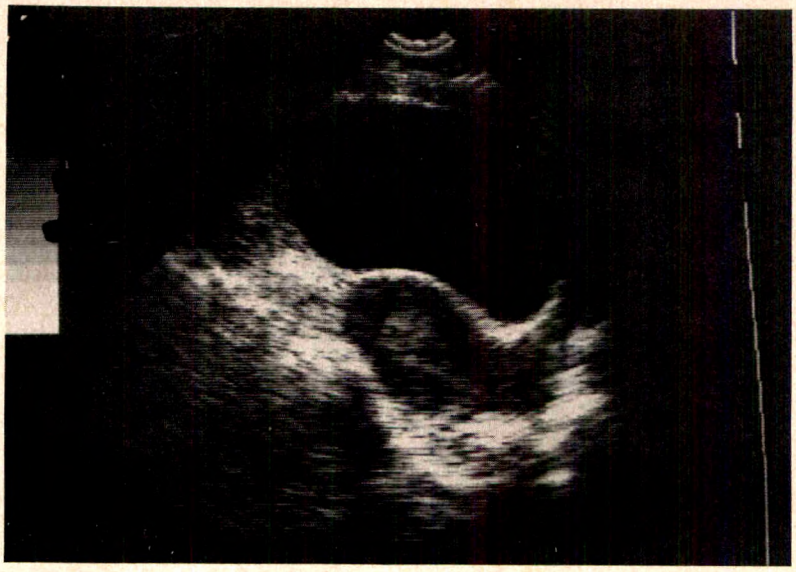

Fig. 2. Longitudinal sonogram of a postmenopausal uterus with variable echogenicity of the uterine cavity.

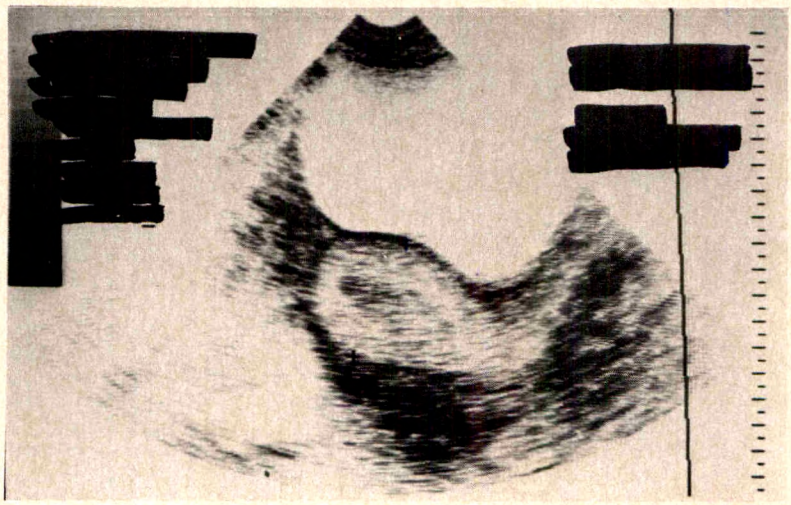

Fig. 3. Longitudinal sonogram of a postmenopausal uterus with an enlarged uterine cavity.

Table II. Pathologic findings in 12 patients with sonographic indications of malignancy

Patient No.	*Age*	*Sonographic findings*	*Findings at curettage or hysterectomy*
1-10		See Table I	See Table I
16	90	Prominent endometrial echo compatible with uterine malignancy	Surgeon unable to perform curettage because of stenosis; no malignancy at hysterectomy; atrophic endometrium; cavity not mentioned by pathologist
17	70	Slight increase in anterior-posterior diameter of uterus; prominent endometrial echo	Benign proliferative endometrium; endometrial polyp

3 cm and a length of 8 cm. There is a homogenous echo pattern (hypoechoic), and the uterine cavity is not visible (Fig. 1). In this series the sonographic changes indicative of uterine malignancy in the 10 positive cases were a prominent or variable echogenicity of the uterine cavity (eight cases) (Fig. 2), enlarged uterine cavity (four cases) (Figs. 3 and 4), enlarged uterus (four cases), and mixed echo pattern of the uterine body and lobular

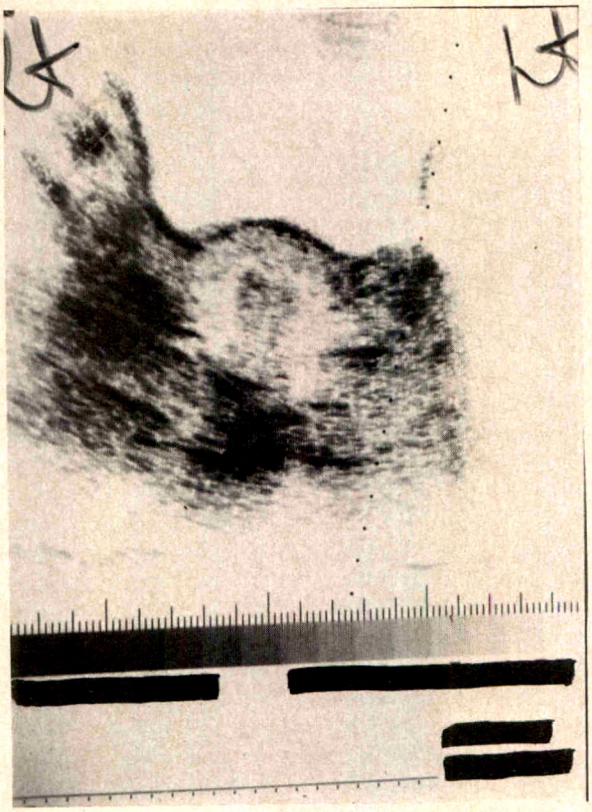

Fig. 4. Transverse sonogram of the uterus in Fig. 3.

uterus (two cases) (Fig. 5). The cases of mixed echo pattern and lobular uterus confirmed the report[6] that these changes were evidence of Stage III or IV disease.

Analysis of the five false-negative cases reveals two cases (No. 11 and No. 15) of a superficial endometrial adenocarcinoma with no cavity distortion, consequently there was no sonographic change. The other three cases are nonexplainable, since two cases (No. 13 and No. 14) had Stage III disease and case No. 12 had ⅓ myometrial invasion. With regard to the two false-positive cases, case No. 16 may be explained by cervical stenosis with probable distension of the uterine cavity and case No. 17 is explained by a benign endometrial polyp.

The primary conclusion from these series is that the pelvic sonogram does not serve as a screening test for endometrial adenocarcinoma, since 33% of the cases were missed. As a corollary, however, if a pelvic sonogram is performed and any of the suspicious findings as described are present, surgical investigation is definitely indicated. One question to be resolved is what changes there will be in the uterine cavity in the postmenopausal patient on cyclic estrogen-progesterone. This problem is being investigated by us at this time.

Discussion

Dr. Louis Bartolucci, San Francisco, California. Dr. Chambers has looked into the utility of gynecological ultrasonography in the diagnosis of endometrial carcinoma and uterine sarcoma, a very interesting subject that somehow failed to receive a fair share of attention in the recent, explosive development of this discipline.

It would be useful to know whether or not the sonographer who reviewed the scans used in the study was told of the diagnosis of endometrial carcinoma in advance or was otherwise oriented to the fact that the test was a screening procedure for this lesion. This knowledge would lend support to either way of looking at the reported cases, the retrospective or the prospective one.

Dr. Chambers draws some important conclusions from his study: The first is that ultrasound is not an adequate screening test for endometrial carcinoma because it missed the diagnosis in 33% of his cases. Aside from the general consideration that a diagnostic test capable of 67% efficiency should still be usable if one recognizes its failure rate, I would like point out some other facts that may mitigate this conclusion.

In 90% of the cases of the study in which ultrasound correctly diagnosed an endometrial malignancy, the uterine cavity was visualized and reported abnormal to a variable degree. In the two cases labeled as false positive, a distended cavity was seen in one (No. 16), probably secondary to cervical stenosis, and an endometrial polyp was found in the other (No. 17)—two conditions worth investigating in a postmenopausal uterus. It is more important, however, to observe that in all five cases in which ultrasound failed to diagnose an existing endometrial malignancy, the uterine cavity was not mentioned by the sonographer and presumably not visualized by the scan.

Ultrasonic visualization of the uterine cavity is a relatively easy procedure in a nonpregnant uterus if adequate scanning techniques are observed and modern standard instruments are used. Many authors have reported such techniques in detail,[1, 2] and recently developed, commercial ultrasonic scanners have resolving capability sufficient to show endometrial thickness and texture at various stages of the menstrual cycle[3] or fine motions of the endometrial lining during ovulation induction or other stimulations.[4] The postmenopausal uterus is no exception, except for cases of extreme atrophy or concomitance of large pelvic masses.

In my opinion, a sonographic study of a nonpregnant uterus should always include a description of its cavity, especially when the scan is aimed at detecting endometrial pathologic conditions.

I agree entirely with the second and third conclusions in Dr. Chambers' study. I wish to congratulate him on his valid effort to sharpen our thoughts on this application of gynecological ultrasonography and look forward to hearing about his observations on the postmenopausal endometrium under estrogen-progesterone replacement therapy.

Dr. Charles Plows, Anaheim, California. I think one thing this paper points out is that patients do not have to be bleeding to have endometrial carcinoma. I recall one of my cases in which the patient had been treated for over a year for watery discharge but did not respond. She had an ultrasound scan of her pelvis which revealed a filling defect in the uterine cavity. On curettage it was found she did have adenocarcinoma.

The only thing I would ask Dr. Chambers is how many of these patients were symptomatic? I can understand that inability to assess adequately the pelvis would be indication for pelvic ultrasound studies.

This interesting paper brings to mind that a patient does not have to experience postmenopausal bleeding or irregular bleeding patterns to have adenocarcinoma.

Dr. Simon Henderson, San Francisco, California. I would like to ask Dr. Chambers whether he is actually proposing ultrasonography as a screening test for endometrial carcinoma; if he is, is he just applying this to patients with symptoms, and if not, does he think we should do this on everybody?

I would also like to comment on the use of the smaller diameter hysteroscopes that we now have available for making a diagnosis of endometrial carcinoma. The Hamou hysteroscope can be used in the office even in postmenopausal women with very small cervices. Paracervical block can be used and sometimes no anesthesia at all. Hysteroscopy has certainly been done in France in clinics for some time and is being used now in offices and clinics in this country for intrauterine diagnosis.

Dr. Conley G. Lacey, San Francisco, California. I, too, have been interested in the use of sonography for the diagnosis of pelvic masses and endometrial cancer. In reviewing this technique for the diagnosis of pelvic pathologic conditions several year ago at Tulane Medical Center, we found that sonography was often inaccurate and produced as many false positive findings as false negatives. In Dr. Chambers' series a false positive result was followed by surgery that caused the death of one patient. In my experience the misinterpretation of sonographic findings is a relatively common error in clinical practice, and at the two extremes of error, results in life-threatening delay in surgery on the one hand or unindicated laparotomy on the other.

From my experience in several institutions in the United States I have been exposed to many sonography departments. I have learned from this experience that the results of sonography are, of course, directly proportional to the skill of the sonographer. I have also found that most sonographers never see, or examine, the patient. They attempt to correlate what is found on pelvic examination done by someone else with what they see on the sonogram. Consequently, it is very important to correlate the clinical findings with the sonographic findings and not order the sonogram in the first place if there are other clinical imperatives that would suggest that the results of the sonogram will not alter what you do.

Dr. S. Gainer Pillsbury, Long Beach , California. There are situations where additional nonoperative evaluation of the endometrial cavity would be useful in cases of questionable findings on ultrasound. We have just installed a magnetic resonance imaging unit at our hospital and have taken some pictures of the uterus. You get absolutely beautiful, clear pictures of the endometrial cavity and the uterus in many instances. This might be of some value in cases where the findings are in doubt.

Dr. Joseph Yon, Seattle, Washington. I want to echo

what Dr. Lacey said about the poor results that we get a lot of the time, trying to evaluate pelvic masses with ultrasound, but I have had four patients in the past few years who, either because of their body habitus or vaginal stenosis, were difficult to examine, and none of whom had any vaginal bleeding. And I got the ultrasound scan just to see what it was I was not feeling. Two of them had Stage IV endometrial carcinoma and two of them had Stage I, and were diagnosed at curettage. And I would also echo what was said about nuclear magnetic resonance imaging. They are excellent; you can even tell the depth of myometrial invasion on some of the good NMR scanners, which is really going to be of help in preoperative evaluation of endometrial carcinomas.

Dr. Chambers (Closing). Dr. Bartolucci, Dr. Unis, who was the co-author with me on this paper, a radiologist, and I reviewed all the sonograms. But these reports were the reports made by the radiologist before the surgical procedure. In those five cases in which there were false negatives, we could not see any cavity on review of the cases, although this was not mentioned in the report.

Dr. Henderson, I am not proposing that gynecologic ultrasonography be a screening test. I do not feel that it is indicated. When one of my patients has postmenopausal bleeding, I am not going to order a pelvic sonogram if I can do an adequate pelvic examination and if I can do an endometrial biopsy, or if I have to do a curettage. But I find that with many of the family physicians and many of the internists, this is a means they turn to.

So we are going to have these sonograms and the point that I am making is that if we do get a report that gives a positive finding, then we should investigate it. I definitely agree with Drs. Pillsbury and Yon that nuclear magnetic resonance imaging is going to be an excellent test, but obviously, expense comes into play with it.

Partial colpocleisis

Charles F. Langmade, M.D., and Joseph A. Oliver, Jr., M.D.
Pasadena, California

Partial colpocleisis, in comparison with complete colpocleisis, offers several advantages. The most obvious advantage is the avoidance of recurrent prolapse in sexually nonactive, older patients. Historically, colpocleisis has been reported to produce stress incontinence, which may be avoided by partial colpocleisis. Careful attention to avoiding anterior wall adhesions by leaving anterior and posterior vaginal walls separated and a very small, nonfunctional vagina will prevent scarring with fixation at the bladder neck, which in most instances will result in stress incontinence. To leave a functional vagina in an elderly widow, not active for many years and with no plans for sexual activity, will leave the patient with the possibility of recurrent prolapse. Partial colpocleisis, a relatively short procedure with minimal blood loss and with careful attention to the avoidance of scarring between the anterior and posterior walls, will obviate the reported stress incontinence following complete colpocleisis. One hundred two cases from 1970 will be analyzed and reported. (Am J Obstet Gynecol 1986;154:1200-5.)

Key words: Prolapse, partial, colpocleisis

Berkely and Bonney[1] once stated that the possibility of curing a case of procidentia in which the entire uterus had been removed, without narrowing of the vagina and therefore preventing sex relations, is almost nonexistent. To correct this problem was of great importance to many gynecologic surgeons of the day. Le Fort,[2] in 1825, reported his operation, but this procedure was prone to produce postoperative stress incontinence and was done for uterine prolapse. Telinde, in discussing Phaneuf's 1952 article,[3] pointed out that in Le Fort's procedure and the modification by Goodall and Powers,[4] the scarring produced a downward pull at the bladder neck and contributed to stress incontinence. Symmonds et al.[5] and Phaneuf[6] did not address the problem of postoperative stress incontinence. Anderson and Deasy[7] presented 16 cases in which the patients underwent hysterocolpectomy by their method; of these patients, three had postoperative stress incontinence (personal communication). Goldman et al.[8] reported on 118 patients who underwent the Neugebauer-Le Fort operation[2, 9] and had a 10% incidence of urinary incontinence and three failures. Pratt and Baker[10] reported urinary stress incontinence following Le Fort's operation, as did Hanson and Keetle[11] and Heany.[12]

An operation designed to prevent any chance of recurrence and to prevent stress incontinence would be the ideal procedure. Patients can make the decision as to further and future sexual activities. Widows who are 80 years of age and who have been both widowed and nonactive for 20 years can certainly be fairly certain that they will not again become sexually active.

Material and methods

During the years 1970 to 1984, a total of 102 patients underwent a type of partial colpocleisis designed to prevent stress incontinence and also to ensure that there would be no recurrent prolapse. These patients ranged in age from 53 to 95 years, with an average age of 75.4 years. Fifty-one had had previous surgery, 30 abdominal and 21 vaginal surgeries. Six had had previous Cooper's ligament support of vaginal vault prolapse.[13] Twenty patients had preoperative urgency incontinence, and 23 had preoperative stress incontinence. Twenty-eight patients were taking imipramine (Tofranil), 25 to 75 mg, for urgency incontinence prior to surgery. Twenty-four patients had had pessary trials that were not satisfactory. All the patients used vaginal estrogen cream prior to surgery and did pubococcygeus muscle exercises. They were all taking oral estrogens unless breast problems contraindicated this therapy.

Operative technique. The two main procedures done were (1) vaginal hysterectomy, anterior and posterior repair, and partial colpocleisis in 60 cases and (2) anterior and posterior repair, enterocele repair, and partial colpocleisis in 42 cases.

In the vaginal hysterectomy group, the uterus was removed, the peritoneal portion of the enterocele sac was ligated high, and the uterosacral ligaments in the area of the ligaments were plicated in the midline with interrupted chromic 0 sutures. The area of the ligations is mentioned because if sections are taken through these areas many times, the ligaments will no

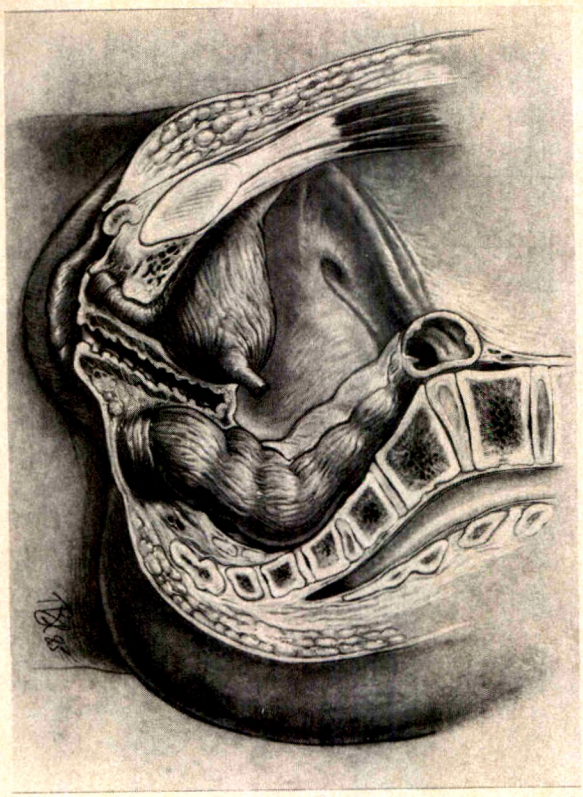

Fig. 1. A "pencil-sized vagina" is formed with adequate distance between the anterior and posterior walls to obviate scarring and downward pull at the bladder neck.

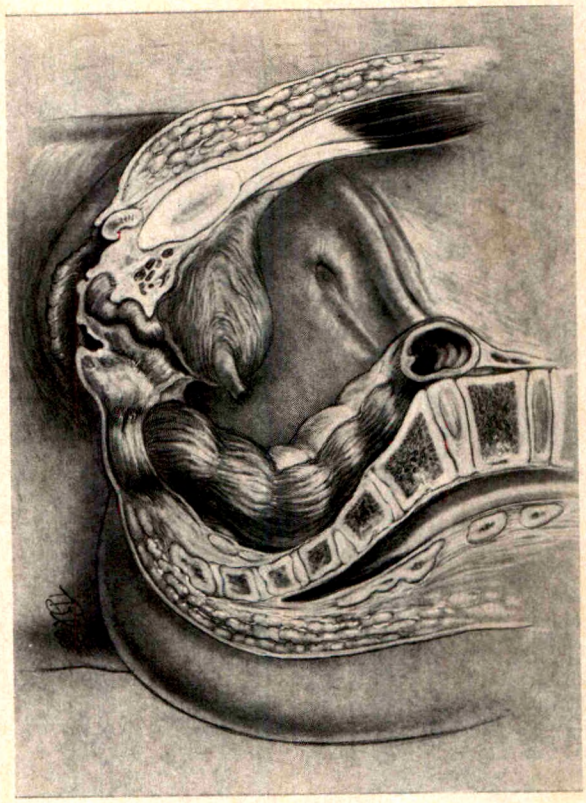

Fig. 2. Complete colpectomy leads to scarring, with distortion of the urethra and bladder neck and subsequent downward pull at the bladder neck.

longer exist. The anterior wall mucosa is dissected over the cystocele, and the vesicovaginal fascia is imbricated with chromic 0 interrupted sutures. The most important step in the anterior repair is to remove very little vaginal mucosa. Removing too much vaginal mucosa leads to scarring under the bladder neck, with subsequent downward pull and stress incontinence, as described by Phaneuf.[3] If scarring from previous surgery is present, it should be lysed and the mobility of the bladder neck established, especially in patients with stress incontinence. In the enterocele and cystocele group that had had previous hysterectomy, the treatment was the same.

The posterior repair is done in such a way as to form a pencil-sized vagina with the anterior and posterior vaginal walls remaining apart, thus excluding scarring in this area and postoperative stress incontinence (Fig. 1). If a complete colpectomy is performed, the lack of vaginal mucosa under the bladder neck leads to scarring and distortion of the urethra and bladder neck (Fig. 2).

A V-shaped incision is made high on the vulva between the labia minora and the labia majora (Fig. 3) and continued downward to the rectum. The uppermost part of the incision starts just below the urethral orifice and extends down to the midportion of the perineum, just above the rectum. A midline incision is made up to the peritoneal reflexion, the levator muscles are identified on either side, and the excess vaginal mucosa is removed. On the posterior wall, a considerable amount of mucosa is removed. The center area,

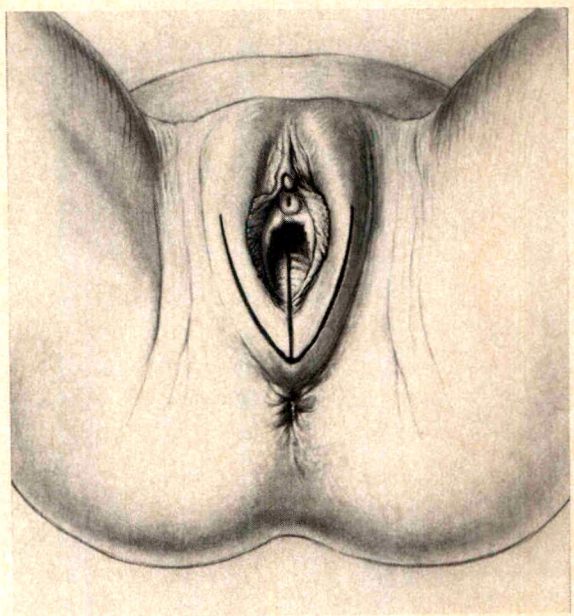

Fig. 3. A V-shaped incision is made high on the vulva between the labia minora and the labia majora down to the rectum.

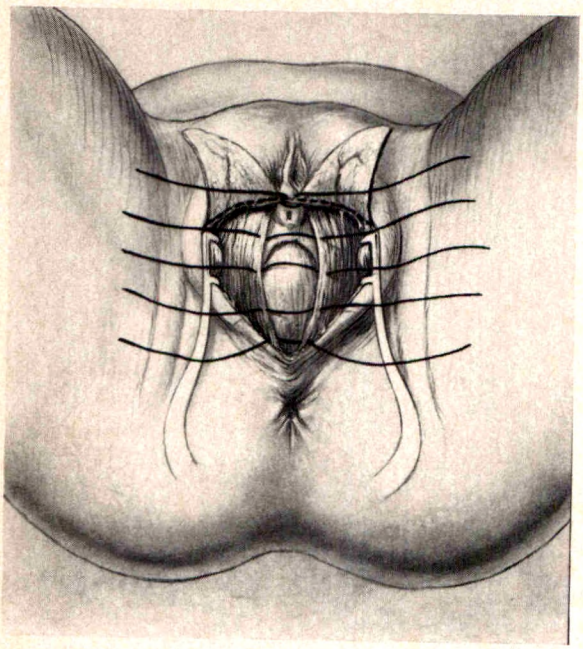

Fig. 4. The levator muscles are sutured in the midline from the urethra to the rectum.

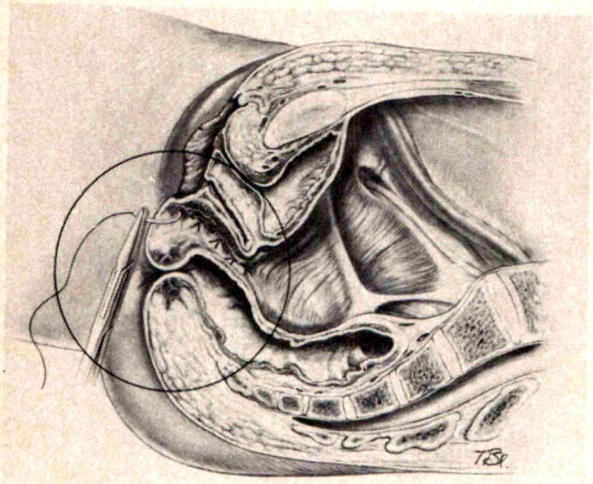

Fig. 5. The interrupted sutures are brought out on a straight line to the fourchette to greatly decrease the diameter of the vagina.

between the urethra and the rectum, is sutured with interrupted chromic 0 sutures on large Mayo needles (Fig. 4). The suturing is done from the peritoneal reflexion on a straight line out to the fourchette, greatly reducing the diameter of the vagina but leaving the anterior and posterior walls separated (Fig. 5).

The posterior vaginal wall is closed with continuous locked chromic 0, and more interrupted sutures close the superficial perineal muscles and fascia. The perineum is closed with subcuticular suture of the same

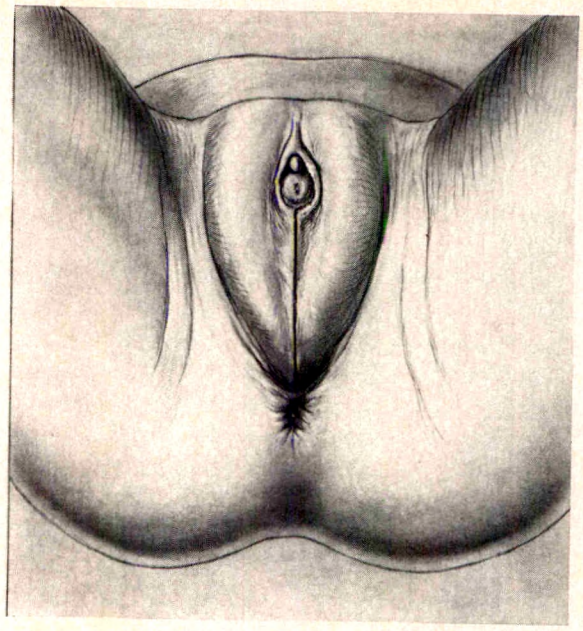

Fig. 6. The perineum is closed with a subcutaneous and subcuticular running suture up to the urethra. The opening just below the urethra admits the size of the little finger for about 10 cm.

chromic 0 suture used to close the posterior vaginal wall (Fig. 6).

Penrose drains were placed in the perineum in 74 cases.

Antibiotics were used postoperatively in all cases. Procaine penicillin, 1.2 million units, given intramuscularly every 8 hours, and streptomycin, 750 mg every 12 hours in six doses, were used prior to 1981. No severe complications from the streptomycin were noted, and only rare skin rashes from the penicillin were noted. In 1981, tobramycin sulfate was given, 80 mg as an average, every 12 hours intravenously, with aqueous penicillin, 2.5 million units, given every 6 hours intravenously. Patients who were sensitive to penicillin received clindamycin (Cleocin), 300 mg, given every 6 hours intravenously for 72 hours. One case of temporary diminished urinary output was attributed to tobramycin sulfate but resolved spontaneously in 4 days after the drug was discontinued.

Results

Failure. There were no failures or recurrent prolapse in any of the 102 cases. The follow-up varied from 1 year to 14 years, with an average of 2 years 11 months.

Operative time and blood loss. The operation is easy to perform and was done in an average time of 78 minutes. Patients were an average of 75.4 years old. It is well to have a short operating time and low amount of blood loss in this age group. The average blood loss

was 231 ml, which is a reasonable amount for this age group and a procedure accompanied by no failures.

Stress incontinence and urgency incontinence. Of the 102 patients, only two had stress incontinence postoperatively, and both of these patients had had stress incontinence preoperatively; in no instance was stress incontinence produced by the operation. Of the 20 patients with urgency incontinence, 15 had the same symptoms postoperatively.

Voiding time was from 3 to 21 days, with an average of 6.1 days. Those patients going home with a catheter were 16 in number, and of these, 10 voided on return to the office in 1 week with catheter removal, five voided in 2 weeks, and one in 3 weeks. All had an indwelling urethral Foley catheter No. 14 with leg bags. All eventually voided.

Hospital stay averaged 9.4 days, with a range of 6 to 19 days. The only cause of prolonged hospital stay was an elevated temperature.

There were no deaths in the series.

Complications. Two patients continued to complain of stress incontinence postoperatively. Both had had stress incontinence before surgery. Forty-three patients had urinary incontinence postoperatively; however 27 recovered and 15 continued to have urgency incontinence. One patient had urgency incontinence postoperatively who did not have it preoperatively. One patient had a temporary renal toxic reaction to tobramycin, which resolved spontaneously. One patient had pyelonephritis with septicemia, which cleared with treatment, but the patient was hospitalized for 19 days. This patient increased the average hospital stay a significant time.

No transfusions were given, and no hematomas or abscesses were diagnosed.

No patients changed their mind in regard to partial colpocleisis or sexual intercourse after surgery.

There were no cases of pulmonary embolism, and the one patient with a temperature of 104° F was diagnosed as having a drug reaction caused by sulfisoxazole (Gantrisin). All the patients discharged with catheters in were receiving some type of catheter coverage, such as Gantrisin or nitrofurantoin (Furadantin) and, in some cases, tetracyclines.

Forty-four patients had a postoperative febrile course, with an average temperature of 100.6° F in the first 72 hours, with subsequent reduction to normal within 24 hours. The range of temperature was from 100° to a high of 104° F. Six patients had an average temperature of 100.7° after 72 hours, with a range of 100.4° to 101.7° F. All patients were afebrile on discharge. Eleven patients had postoperative pyuria, but all patients went home with negative urine, even though 16 patients went home with an indwelling catheter.

Comment

One hundred two patients undergoing partial colpocleisis had no recurrent prolapse; there were only two cases of postoperative stress incontinence. There were no major complications in the series, and operating time was short and blood loss minimal.

Discussion

Dr. Frank LeCocq, Yakima, Washington. In 1952 Emil Novak stated that he had not seen a case of vaginal prolapse that could not be corrected from below, but many voices have been raised since that time to dispute his assertion. Gynecologic surgeons have described the suspending of the vagina from the rectus fascia, the pubis, the sacrum, and Cooper's ligaments, as recommended by Dr. Langmade. All these procedures have been successful. A properly performed vaginal procedure again emerges as a primary repair for vaginal prolapse, and it takes advantage of the long-recognized fact that perineal tissues heal rapidly and with little reaction.

This discussion allows me to say a word about today's somewhat tenuous state of vaginal surgery. Dr. Dave Nichols, of Providence, Rhode Island, recently noted the absence of vaginal surgeries in reviewing American Board Candidates' case lists. Vaginal surgery may indeed be the victim of the increasing amount of scientific material crammed into the residency years. Of increas-

ing importance with the vaginal approach is the usual reduction in days of hospitalization. In this era of diagnosis related groups, millions of dollars are saved with each day's reduction.

This Society can boast of having leaders in the surgical repair of vaginal prolapse, since over the years the contributions of William Bradbury and Jess Rust, as well as of Charles Langmade, have been presented to this Society.

Drs. Langmade and Oliver have presented an impressive number of patients who must be divided into two distinct groups. The first sixty patients described are suffering from uterine procidentia and have been treated with the conventional vaginal hysterectomy, with excision and ligation of the enterocele sac, and with a partial colpocleisis. The second forty-two cases were diagnosed as vaginal prolapse, and the patients were possible candidates for the author's previously described Cooper's ligament suspension. In previous papers discussing Cooper's ligament suspension, the author has alluded to the treatment by vaginal colpocleisis, but the numbers and results have not been recorded. Thus the author has not ignored the vaginal approach in the past but now evaluates its advantages.

I wish to make a few remarks about technique. In 1961 the late William Bradbury, in his usual charming manner, presented a paper on subtotal vaginectomy for the treatment of vaginal prolapse. He noted that, in ancient times, Euryphone suspended the patient by her feet for 24 hours as an appropriate treatment for vaginal prolapse. The success of this treatment is unreported, but I suspect that no further complaints were forthcoming from the patient. Scarring of the tissues with a red-hot iron or needles was also an ancient treatment for vaginal prolapse.

In 1887, Léon Le Fort, speaking to the Paris Surgical Society, presented the first successful surgical procedure for vaginal prolapse. The disadvantage of covering the cervix, producing a nonfunctional vagina and, all too frequently, stress incontinence, has largely removed the procedure from our armamentarium. A modified Le Fort operation, called a lateral Le Fort by Cusier, may allow a functional vagina. One of our members, Morton Stenchever, of the University of Washington, is an advocate of this approach and reports excellent results with no recurrences. He stresses, however, limiting the proximation of the anterior and posterior walls at the bladder neck, thus avoiding urinary incontinence, and he further stresses "self-esteem" when the patient can observe that she still has a vagina.

For many years we have utilized a technique similar to that described by Dr. Langmade with considerable success. Care must be taken to complete a high ligation of the entire enterocele sac to avoid recurrence of prolapse or, rarely, a so-called anterior enterocele. We have also observed that the presence of a vagina, although minuscule, might result in a better self-image for the patient. If stress incontinence is severe, the Pereyra-Stamey-Raz procedure can assist with little additional operating time. Originally proposed by Randall and Nichols in 1981, suturing of the vaginal apex to the right sacrospinous ligament is helpful in the vaginal approach. This procedure has been successfully performed and described by Warren Jones and Joe Markee, of our Society.

We differ in the choice of suture materials, using the polyglycolic acid materials instead of catgut. Drains are not used in the perineum as described, but only at the vaginal apex in an extraperitoneal position. I question whether drains are necessary in the perineum, in view of the excellent and usual healing of perineal tissues.

Routine prophylactic antibiotics are not used except in cases of premenopausal vaginal surgery or if postoperative morbidity occurs. Have the authors found the routine use of antibiotics to be of enough value to offset the drug complications that they describe herein? Needless to say, the indwelling catheter always warrants prophylactic urinary antibiotics. The suprapubic cystocatheter improves the postoperative bladder management and does not require medication, but it does require more monitoring.

In regard to sexual function, I always remember our beloved babysitter, who had an orange-sized procidentia, the kind that makes the surgeon's eyes gleam and operating room nurses gasp. After she assured me of having had many years of celibacy, a vaginal procedure similar to Dr. Langmade's was performed. She felt so well that she returned to her senior citizen's dancing group, met an older gentlemen who proposed marriage, and returned to me, asking that her vaginal function be restored. Although you cannot always trust the patient's sexual aspirations, I would agree, in general, with the author's criterion for his selection in this regard.

Again, my congratulations to Drs. Langmade and Oliver for this excellent contribution. In this and other papers, Dr. Langmade presents a lifetime of experience with surgery for vaginal prolapse by both abdominal and vaginal routes and represents one of the country's foremost authorities in this type of surgical repair.

Dr. Jesse Rust, San Diego, California. I didn't hear you say anything about preventing stress incontinence. Do you put in a Kelly stitch in the anterior wall repair?

I wish to make one other comment. You mentioned the Mersiline mesh sacral colpopexy. We reserve that operation for the prolapsed normal-caliber vagina, with the vaginal repair done only for the voluminous prolapses.

Dr. William Graves, San Francisco, California. I'd like to thank Dr. Langmade for another surgical-technical contribution.

I'd like to ask, How many patients were successfully using vaginal pessaries during the period of this study, in contrast to the 24 unsuccessful pessary trials in this group of women with genital prolapse?

Dr. Paul Shively, San Francisco, California. I presented a similar paper at Salishan in 1968, and my series was small. In fact, it was so small that it was not in the

official GRAY JOURNAL but was recorded in the proceedings of the Pacific Coast Society. The study was on enterocele and partial colpocleisis. I think that partial colpocleisis is an excellent operation for a very small, select group of patients.

DR. LANGMADE (Closing). Dr. LeCocq, your discussion was flattering, and I appreciate very much your kind words, especially when you have had so much experience in vaginal surgery.

You are correct. The teaching of vaginal procedures these days leaves something to be desired in the medical school and county hospital settings. My thoughts are that the 65-year-old and over patients with prolapse now are seen as private patients under Medicare, and the older group is not seen in medical school and county hospital training centers. Further, other scientific programs fill more of the curriculum than do vaginal operations.

You are absolutely right in regard to draining of the perineum. We alternated our drains, and it did not seem to make a great deal of difference whether we drained them or not. We did not drain the vaginal vault in any case.

Foley catheters are considered to be old-fashioned today; however, none of them plugged up, and none of the patients seemed to mind too much about going home with a leg bag.

Dr. Rust, in regard to your question of management of stress incontinence, we did an anterior repair and were fortunate to have as many patients fall into the 85% good results that we would expect with an anterior repair. The only two patients with postoperative stress incontinence had stress incontinence prior to the surgery. Your remarks comparing the voluminous vaginal vault prolapse with the telescoping type are most interesting, and we know that you treat the bulging type with vaginal repair and the telescoping type with a Mersalene strip. You mentioned that we do do some vaginal procedures, and I have been trying to tell you that for years.

Dr. Graves, in regard to your question on the use of pessaries in these patients, we did try pessaries for 24 patients, and they did not tolerate them well. How many in general we see, I can't tell you exactly. However, we probably see three or four patients every month who are doing well with the pessary and would require no surgery.

Dr. Shively, I am sorry I didn't mention your contributions in the paper you presented in 1981. It was a small series, but it was a start, and most certainly we do appreciate your contribution.

A large community hospital's experience with an obstetrics-gynecology risk management committee: Quality assurance

Douglas Der Yuen, M.D.
Seattle, Washington

In an era when medical-legal suits and awards are escalating, a major metropolitan hospital in Seattle, Washington, has developed a plan to identify and effectively deal with problem physicians, improve patient care, and reduce medical liability for the institution. The Department of Obstetrics and Gynecology of The Swedish Hospital Medical Center formed a risk management committee that met regularly to monitor and evaluate clinical complications and questions of professional incompetence or physician impairment. A system for detecting such cases was established through liaison with other hospital peer review committees or any physician or nurse who was privy to specific information and willing to submit it in writing. Cases were carefully and objectively analyzed and evaluated as to their significance and severity. Single serious errors in case management were brought to the attention of the offending physician. Chronic offenders had privileges restricted or revoked with the approval of the hospital executive committee. This has resulted in improved medical care for patients and a reduction in medical-legal action against the hospital. (Am J Obstet Gynecol 1986;154:1206-10.)

Key words: Risk management, quality assurance, peer review

Professional liability is one of the most disturbing problems presently confronting both obstetricians-gynecologists and hospital administrators in the United States. Dramatic increases in the frequency of suits, astronomical awards to claimants, and skyrocketing malpractice insurance premiums are merely the tip of the iceberg as regards a crisis that is threatening the future of our specialty. Preoccupation with this problem is altering the pattern of obstetric practice in a manner not always to the patient's benefit, since physicians feel compelled to practice "defensive medicine" in response to the ever-present threat of litigation. Tests and procedures of questionably genuine indication further escalate medical costs. In addition, many experienced and competent physicians are finding it expedient or even necessary to drop their obstetric practices altogether.

Everyone currently facing this dilemma recognizes there is no immediate solution. Neither attorneys nor insurance carriers can be expected to resolve the problem, and a legislative solution in terms of tort reform is not likely to be forthcoming in the foreseeable future. Hence, in an attempt to reduce the number of poorly managed cases in its obstetrics unit and on its gynecologic service, The Swedish Hospital Medical Center, a major metropolitan hospital in Seattle, Washington, instituted an obstetrics-gynecology risk management committee to: (1) document instances of substandard care, (2) deal appropriately with poorly qualified physicians, and (3) ultimately improve the quality of patient care and reduce medical liability for both the medical staff and the institution.

The Swedish Hospital Medical Center is a 652-bed private teaching institution in Seattle, Washington; Swedish serves as the major metropolitan maternity center for Seattle, Washington, with approximately 3600 deliveries annually and more than 20,000 surgical procedures annually, of which more than 3500 are gynecologic. The central institution was founded 75 years ago as The Swedish Hospital, and, in 1978, the present title was adopted on merger with The Doctors Hospital, Seattle General Hospital, and Maynard Hospital, with the amalgamation of the respective medical staffs. Among these staff members were 75 obstetricians-gynecologists, nine practicing strictly gynecology, and 68 family practice physicians with obstetrics and gynecology privileges. Within this large group of practitioners there existed a wide spectrum of training, experience, and competence; some members are certified by their respective boards, and others are not. Because of this wide variance of skills and training, individual staff privileges are carefully reviewed annually by the chief of obstetrics and gynecology and the full-time department director and teaching coordinator.

The Swedish Hospital Medical Center is fortunate to have a full-time teaching administrative director for

From the Department of Obstetrics and Gynecology, The Swedish Hospital Medical Center.

obstetrics and gynecology who is board-certified in both obstetrics and gynecology and clinical genetics. His position is supported by three full-time hospital-based associates: two perinatologists and a doubly trained internist-obstetrician. The hospital also employs a full-time neonatology staff. In addition to providing consultative support for the active staff, these physicians maintain a referral practice and provide a wide variety of reproductive laboratory support facilities.

The Swedish Hospital Medical Center also provides an important teaching function in the Seattle medical community, with four obstetrics and gynecology clinical residents from the University of Washington program (20% of the total staff) present at any given time, and providing obstetrics and gynecology clinical experience for the institution's own 20 family practice residents and family practice residents from Providence Hospital.

In 1982, after considering the rapidly worsening medical-legal climate, both locally and nationally, the elected chief of obstetrics and gynecology and the administrative director of obstetrics and gynecology expressed to the hospital administration their opinion that it was necessary to monitor obstetrics and gynecology practice in a structured, orderly fashion, in the hope of reducing mistakes of medical judgment and incidents of negligence. The administration responded with encouragement and assurance of support. Hence, with the consent and support of the obstetrics and gynecology and family practice staff, an obstetric-gynecologic peer review committee, known as the obstetrics and gynecology risk management committee, was formed. It was recognized that members of this committee should be carefully selected to discourage allegations of bias, conspiracy, or restraint of trade. Accordingly, a representative mix of respected practitioners in obstetrics and gynecology, including various premerger hospital staff members, different subspecialty groups, and family practitioners, was arranged to form a seven-person committee appointed by and including the chief and the director of the obstetrics and gynecology service.

Since its inception, the risk management committee has met regularly on a quarterly basis, and in emergency sessions, to consider and evaluate alleged physician impairment, single flagrant errors in clinical practice, or repeated episodes of substandard patient care. It was made known that the committee would accept input from other hospital practice committees, such as the obstetric mortality and morbidity committee, the operating room committee, the surgical tissue committee, and the quality assurance committee, as well as from any individual physician or nurse wishing to submit a complaint or evidence in writing. In each case, the initial task of the committee was to carefully and objectively determine the veracity of the charges by scrupulous review of the medical records and/or testimony of witnesses. It was considered vital to guard against any untrue charges that might have been maliciously motivated, as by jealousy, resentment, or overzealous competition for patients. Care was taken to eliminate differences in personality or in temperament as criteria for medical competence; in addition, "cookbook rigidity" of practice or technique was watched for as a possible basis for charges. It was always kept in mind that the absolute rights and wrongs of medicine may be too hard to define and are often subject to interpretation.

In many cases it was determined that no serious problem existed. With minor chronic problems or single errors, the committee made the physicians aware of the problems and worked constructively with the offenders to help them improve. Specifically, (1) interviews were always offered and sometimes insisted on with the physician in question; (2) written follow-up was sent, offering help—primarily suggesting more frequent use of consultation in difficult cases or problem areas and/or continuing medical education focusing on areas of demonstrated weaknesses.

When a single serious or recurrent problem was identified, the physician reviewed was asked to appear for a hearing before the committee. All business conducted by the committee was kept in strictest confidence. Complete factual minutes of all proceedings have been kept under lock and key, available only to the chief and the director. According to the hospital's legal counsel, these records are not subject to subpoena.

In accordance with hospital bylaws, the risk management committee could only recommend that action be taken by the executive committee, except in cases in which continued practice by a physician was deemed a clear danger to patients; then the chief of the department or the hospital chief of staff could exercise his authority to summarily suspend the physician's privileges, pending outcome of the investigation.

The hospital bylaws have subsequently been amended to permit greater flexibility by the risk management committee and departmental chief to restrict physicians' privileges in situations not warranting summary suspension of all privileges. Reports and summaries of the committee's recommendations were transmitted to the executive committee for definitive action, and, when necessary, to the hospital board of trustees and administration. All action taken strictly followed hospital bylaws' procedural codes so there would be no interference with the offending physician's right to due process.

It should be emphasized that without the wholehearted support of the hospital executive committee,

chief of staff, and administration, the existence and function of the risk management committee would not be possible. As the committee's effectiveness in surveillance became clear, it earned the respect and gratitude of the hospital attorneys and insurance carrier and ever-increasingly the respect of the medical staff as well. All involved members found that by eliminating unfit or professionally unqualified physicians from the staff, the collective medical-legal liability for the institution will be greatly reduced, and medical care will be improved, both by protecting patients from the actions of substandard or negligent doctors and by helping those doctors to improve their performances.

During its three years of existence, the risk management committee, with the support of the executive committee, has revoked full staff privileges of four chronic offenders in obstetrics and gynecology. In addition, three other physicians who were found to be clearly deficient in specific areas of practice underwent appropriate privilege restrictions.

Farmers Insurance Company, the liability carrier for the hospital, indicated that there has been an extremely low number of claims made against The Swedish Hospital Medical Center since the inception of the risk management committee. The company stated that they consider this particularly impressive in view of the size and volume of the obstetrics-gynecology service and the ever-increasing numbers of high-risk patients referred to the institution. Their records indicated that the departmental risk and quality control process has had some impact on reducing medical liability, although this is difficult to verify precisely. Comparisons of claims made against other hospitals in the area could not be validly made, since none are comparable in volume or numbers of high-risk patients cared for. Comparison of premerger to postmerger suits is not yet feasible. Three years of committee activity is too brief a period to evaluate adequately and in addition, in any specific cases, several years may elapse before a suit is generated. The Swedish Hospital Medical Center attorneys likewise feel that the activity of the risk management committee has had a positive influence in lowering hospital liability and have expressed their willingness to provide legal support whenever necessary. Last, the chief and director of obstetrics and gynecology both believe that since the risk management committee began to function, there has been a clear decline in the number of serious incidents brought to the attention of the obstetric mortality and morbidity committee at its monthly audits. This, they feel, is due to both an increased consciousness of the level of medical performance by the department as a whole and a general increased recourse to consultation in difficult cases.

Although there have been reports, particularly from California, of punitive suits brought against hospital peer review committees, to date there have been no legal actions brought against The Swedish Hospital Medical Center or the committee members as a result of peer review actions. It is felt that this is due largely to careful and strict documentation of all charges and actions and scrupulous adherence to hospital bylaws, as well as close maintenance of confidentiality. The committee members have always conducted themselves in good faith, have refrained from personal attacks, and have not discussed cases with other staff members, thereby reducing the likelihood of possible charges of libel or defamation. Although two suits were threatened, they were not pursued once the weight of the evidence against the defendant physicians was made apparent to their attorneys. The hospital insurance carriers have adamantly stated that they would back the committee with lawyers, as well as payment of any damages should they be incurred, an important consideration for any such activity. Members of the committee must have this sort of assurance of coverage by the institutional insurance carrier before assuming any activity.

In summary, there is suggestive evidence that frank and objective peer review in obstetrics and gynecology is possible. To avoid problems, investigation should be prompt, thorough, objective, and well documented. Due process, as defined by hospital bylaws, must be strictly observed. Scrupulous anonymity must be maintained. A supportive hospital administration is essential. Legal coverage by the institutional insurance carrier is mandatory. Above all, the committee must be fair, firm, and honorable.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. Keith P. Russell, Los Angeles, California. With mounting professional liability pressures confronting our specialty, increased attention has been given to strategies designed to combat not only the rising numbers of litigations filed but also the soaring financial stresses. Among suggested approaches have been workmen's compensation type of insurance, trip insurance, policies containing greater deductible provisions, and other modifications. The problems of the various risks and malpractice dangers confronting the physician have been addressed by large numbers of medicolegal seminars, increased instruction at the resident education level, and the establishment of departments of professional liability within our major professional organizations. Three compartments of risk consideration have been approached: early detection, management, and prevention. Although the present article carries in the title "risk management," it is the latter category, "risk prevention," that the problem outlined in this excellent article addresses. By a method of rigid peer

review, the assessment of likely damage to the obstetric patient in this institution has been attacked by curtailing or terminating practice privileges of serious offenders within the department.

This matter of peer review has always been a perverse, thankless, and indeed challenging chore within our professional community. It is not a task that is commonly approached with great enthusiasm and is not one for which a reviewer can expect many bouquets. Many of our colleagues go to great lengths to avoid the responsibility. However, studies have repeatedly shown that true malpractice does exist. Many, if not most, suits are brought about by substandard professional care (unknowing, uncaring); in a certain small group these occurrences are repetitive. With this information in mind the author's institution has established a medical staff committee to deal with this specific problem.

This is a tedious process. To date the peer review committee, titled the obstetrics and gynecology risk management committee, has revoked full staff privileges of four chronic offenders in the three years of its existence. Two additional physicians have undergone privilege restriction. In my opinion, this is an excellent performance. Anyone who has dealt with the matter of terminating or eliminating privileges of a fellow professional knows that this entails much time, great soul-searching, and extensive legal activity for due process. In addition the peer review inevitably brings about certain interpersonal strains and stresses. I suspect that a particular problem in the Swedish experience has been the interfacing of family practice privileges within the obstetrics department. As one who had some peripheral involvement in the development of the American College of Obstetricians and Gynecologists—American Association of Family Practice document regarding this matter, I can assure this group that this is not always an easy relationship and usually requires rather constant monitoring.

Some questions inevitably arise on reviewing the present study. Although the author states that strict impartiality is maintained, this is frequently difficult to accomplish in an institution such as a hospital. How does the committee preserve confidentiality? What is the length of term of appointment of the members of the risk management committee? How many physician reviews actually came before the committee? In this day, when nurses consider themselves "patient advocates," what weight is given to nursing complaints and incident reports? Are all cesarean sections in the institution reviewed? Who reviews the reviewers (the committee), those paragons of practice?

In conclusion, I wish to compliment and congratulate the author and his colleagues on this report. These activities reflect a sound procedural concept and one that most obstetric services could and should emulate. The preliminary results speak for a very creditable program.

Dr. Gilbert A. Webb, San Francisco, California. I would like to commend the developing of this committee, but I do have one major objection. I think the motivation is inappropriate. I think our motivation should be to enhance the quality of care in an institution, not to protect ourselves from risk. Therefore, I would suggest changing the committee title to quality care committee rather than risk management committee.

Dr. William Hindle, Honolulu, Hawaii. At the Straub Clinic where I practice in Honolulu, we now number 110 physicians and own our own hospital, so we are highly motivated to control the liability and the risk in the hospital. We have had a similar sort of risk management program for about five years and it has been very successful. We do not have the same sort of results. Hopefully we have carefully selected physicians to join our hospital group, so we have not had to drop privileges or seriously restrict them, except for a few aging senior partners. But I rise to speak to the importance of this issue. As most of you know, I have the privilege of serving as the president of the Hawaiian Medical Association. I spend a lot of time talking about medical malpractice. If one studies the national medical liability trends, particularly as exemplified by obstetrics, it is apparent that the whole system of medical liability is going to collapse in the next few years. This is due to the cost, which is rapidly becoming unaffordable. The premiums are escalating at a rate that even the nation, much less individuals, cannot afford. The time to respond legally to adverse incidents has become so prolonged that it takes about two years for a case to actually be filed and more than six years before it is settled. This delay in the legal system does not serve anyone involved. And the liability caseloads are rising so rapidly in number that the courts are unable to handle them under the present system. It is essential that we physicians exert ourselves as the guardians of the quality of care and as those who determine the standards of practice. This must remain a professional decision, as brought out by Dr. Gilbert Webb and Dr. Keith Russell. Effective physician peer review is critically important. Otherwise, the standards of care will be set by the very aggressive judiciary system, the judges and the juries. They are actively doing this in the courts from their point of view of expansion of human rights and individual rights. The courts are taking away from the physicians the prerogative to set standards of care and standards of practice. So we physicians must exert ourselves in these traditionally professional areas.

By the nature of our practice specialty, we will always have adverse outcomes in a certain number of cases and a certain number of significant complications. These must be dealt with efficiently, effectively, and fairly to all parties involved. There are few cases of true medical malpractice, but the incidence gets distorted because most of the cases that do finally get through the courts and are judged in favor of the plaintiff, overwhelmingly are gross malpractice. However, such unfortunate cases are a very small percentage of the total number of suits that are filed. One approach to the future is for corporate liability responsibility on the hospital level with very strict control and active annual

review of privileges and credentialing specific for each operatice procedure. The critical essential of such a program is physician peer review no matter how difficult it may be to have physicians do this. If we physicians do not do this, it will be done to us.

E. Forrest Boyd, Los Angeles, California. We have been interested in this problem for quite awhile and I would like to bring up the subject of the patient advocate and the patient's perception of what happened. We have had a patient advocate, who was a former nursing supervisor in surgery, for several years in our hospital. We have about 130 total house staff and we are very heavily involved with unions and their type of personnel.

A few years ago, we developed this patient perception concept, and we now have the policy that any time there is an untoward incident or a patient complaint, this is evaluated, usually more by nurses than by doctors. We have several nurses in the Social Medicine Department who immediately contact the patient before they leave the hospital, find out what their perception is of what went wrong or why they were unhappy. It is surprising how many of these problems can be resolved before they even leave the hospital. While I think it is very important and essential that we police ourselves and our peers, I think that what we are being judged by primarily is the public perception of what happens. It may not be the truth, but nevertheless those are the criteria used. We are finding that this tactic is becoming extremely successful. Usually the doctors involved are very concerned and many times are at a loss as to what to do. There is an apparent barrier between the patient or the family and health providers. Many times it is a family-generated problem. But I would like to focus on the concept of patient perception in line with our peer review.

Dr. Der Yuen (Closing). To answer Dr. Russell's question, "How does the committee preserve confidentiality?" we implore each of the members of the committee not to discuss any committee activity with any person outside of the committee. All records are kept in a locked safe so there will be no inadvertent exposure of the minutes to non–committee members. As with any hospital, rumors obviously run rampant and there is lots of discussion among staff and nurses regarding doctors who are being scrutinized. I think it is vitally important not to discuss committee business outside the confines of the committee.

What is the length of term of appointment of members of this management committee? The term is indefinite. If a new chief is elected then he has the option or discretion to keep or dissolve the committee or name new members to the committee.

How many physicians faced committee review? Fourteen were reviewed but only four physicians had their privileges revoked. Three additional physicians had privileges restricted, leaving seven charges that either were dismissed as being groundless or were minor problems that could be dealt with by discussing the problem in a constructive manner.

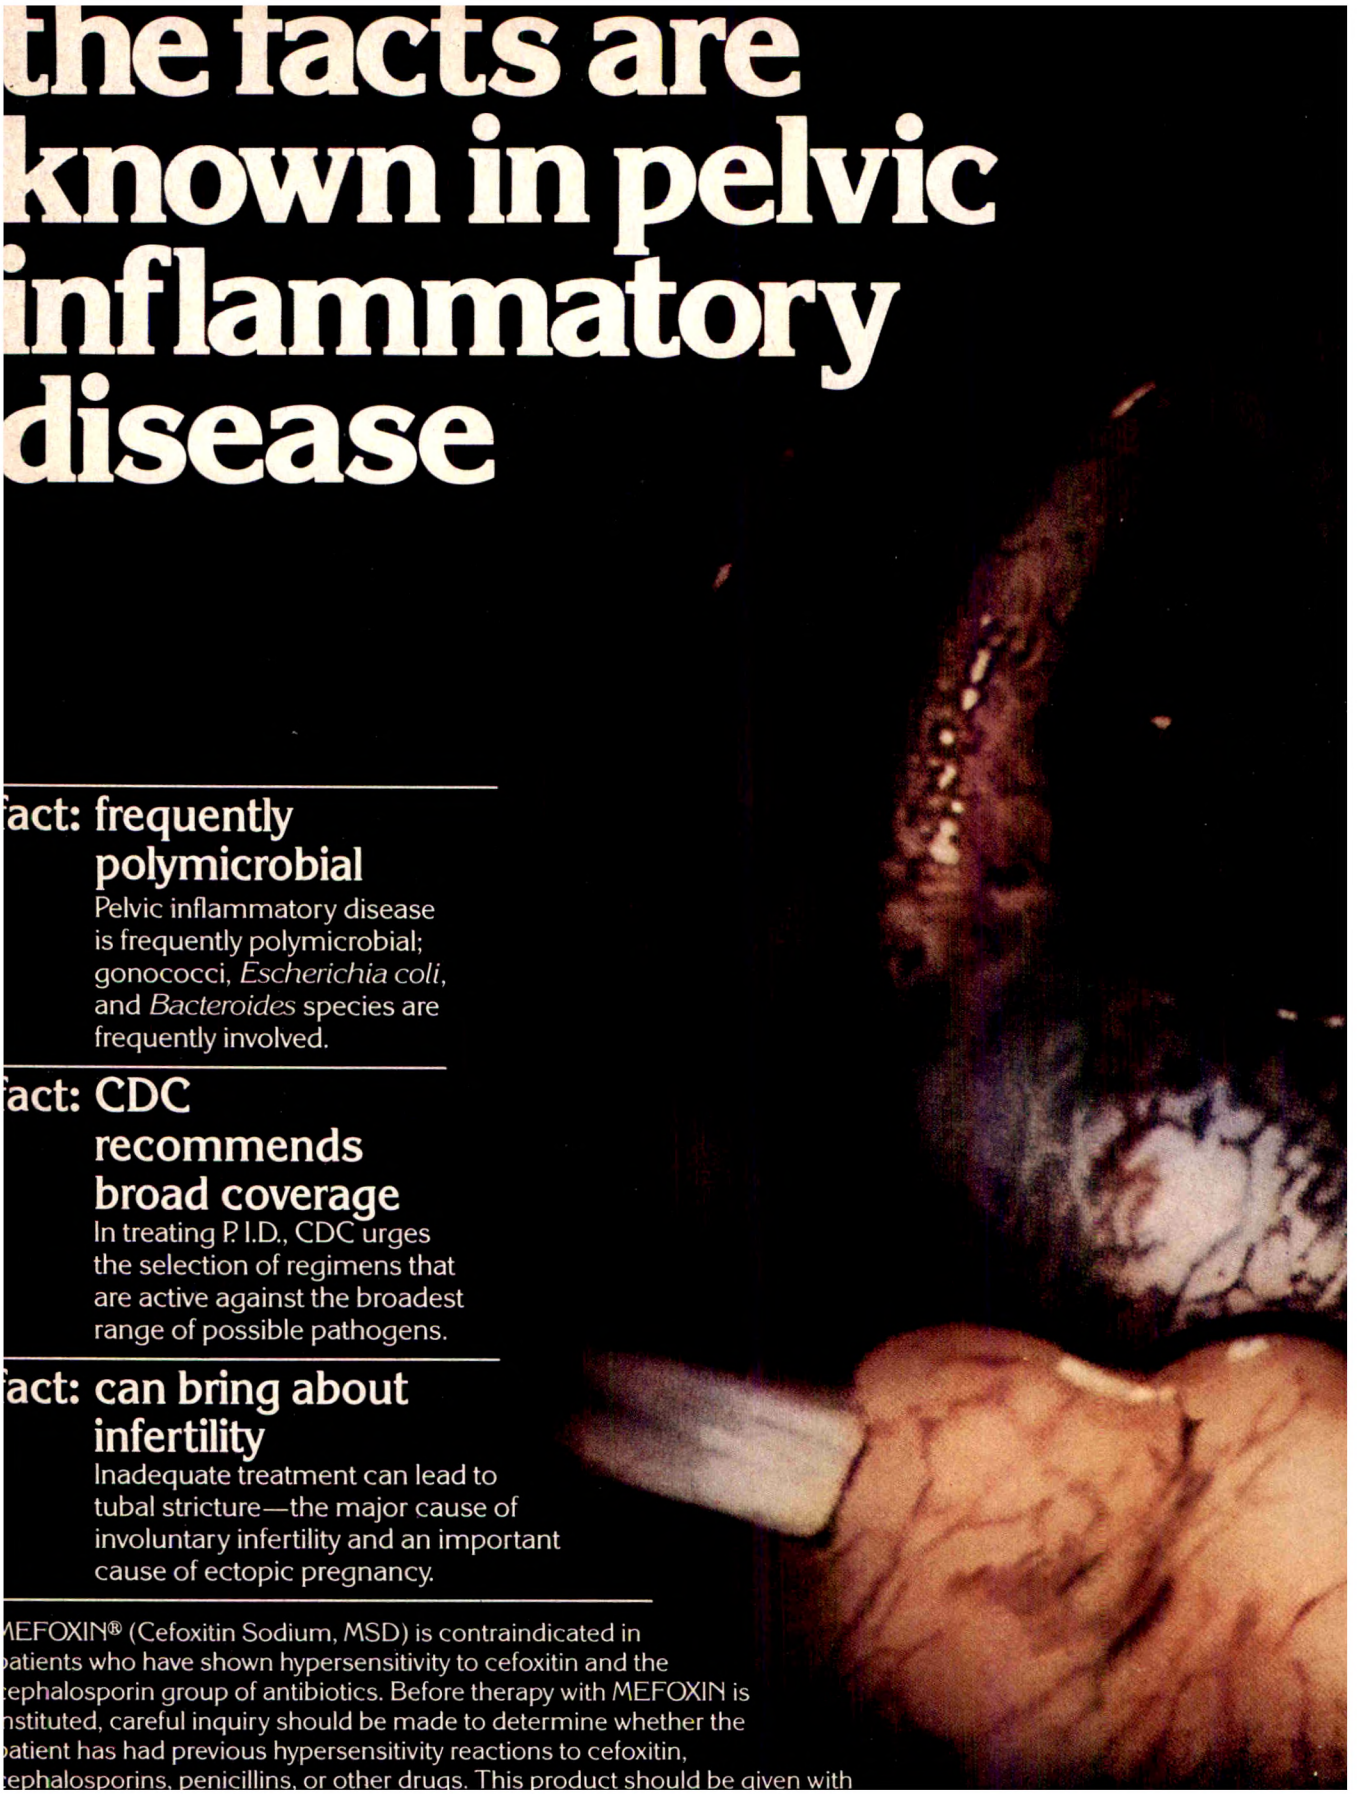
The issue of jurisdictional disputes between physicians and nurses obviously is a sticky issue that is a sign of our times. Nurses are demanding an increased voice in medical decision-making. We have to be very careful that any complaints brought by nurses are not merely a matter of jurisdiction or a personality dispute. Nurses can be very competent observers, particularly in terms of the impaired physician, and sometimes are very astute observers of a physician's performance. We have to give weight to their complaints and comments. As with all complaints, they have to be scrutinized very carefully to make sure there are no motivating reasons other than medical competence or substandard medical care.

Who reviews the committee? Everyone is held accountable to a higher level and we are responsible to the medical executive committee of the hospital and the hospital administrator.

Dr. Webb brought up the question of whether our name should be quality care committee or risk management committee. I concur that the first priority is improvement of patient care. I think the medical-legal concern is secondary. We did not assume the name quality care committee because there is already a multidisciplinary committee of that name within our hospital that deals with broader areas of hospital practices and patient care. "Quality care" is probably a more appropriate term in terms of what we are striving to achieve.

"I'm not going to try anything that's not safe." "I'll forget to take the pill everyday." "I don't need birth control every day like I used to." "I was using an IUD because I can't take the Pill. Now what do I do?" "If it's not easy to use, I won't use it." "Spontaneity is very important to me." "Obviously I want something that's going to be effective." "Is there anything I can buy without a prescription that really works?"

Your patients are bound to have concerns when it comes to replacing their IUD. For most the pill won't be right. Some will resist the mess and interruptiveness of other methods.



But there is another option. The Today® Contraceptive Sponge. The Sponge™ is safe, easy to use, and effective for a full 24 hours. It's 89-91% effective when used consistently and correctly. (Of course, when not used properly effectiveness will be lower: 84-87%.)

So when IUD patients come to you for answers, talk to them about the Today Sponge. For a lot of women, it makes a lot of sense.

For more information, call 800-223-2329 (in California call 800-222-2329)

the facts are known in pelvic inflammatory disease

fact: frequently polymicrobial

Pelvic inflammatory disease is frequently polymicrobial; gonococci, *Escherichia coli*, and *Bacteroides* species are frequently involved.

fact: CDC recommends broad coverage

In treating P. I.D., CDC urges the selection of regimens that are active against the broadest range of possible pathogens.

fact: can bring about infertility

Inadequate treatment can lead to tubal stricture—the major cause of involuntary infertility and an important cause of ectopic pregnancy.

MEFOXIN® (Cefoxitin Sodium, MSD) is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with

Unruptured ampullary ectopic pregnancy.

and in the treatment of P.I.D.†

the facts still favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

PROVEN* FOR 7 SEVEN YEARS

fact: consistent spectrum of activity**

MEFOXIN has maintained a high level of activity against common pathogens in P.I.D. during 7 years of extensive clinical use.

fact: documented clinical efficacy

CDC has recommended that MEFOXIN, in combination with doxycycline, be one of the regimens for the treatment of P.I.D.

fact: safety comparable to cephalothin

MEFOXIN is generally well tolerated. MEFOXIN does not contain the MTT side chain which has been associated with hypoprothrombinemia and, in some cases, clinical bleeding.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

†MEFOXIN is indicated for the treatment of pelvic inflammatory disease caused by *Escherichia coli*, *Neisseria gonorrhoeae* (penicillinase- and non-penicillinase-producing), *Bacteroides* species including the *Bacteroides fragilis* group, *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and Group B streptococci. MEFOXIN is not indicated for treatment of pelvic inflammatory disease where *Chlamydia trachomatis* is present or suspected.

*proven for treatment of, and prophylaxis against, infections due to indicated organisms

***In vitro* activity does not necessarily imply *in vivo* effectiveness.

MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see following page.

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST II reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials and infusion bottles containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY AT THE UNIVERSITY OF MICHIGAN MEDICAL CENTER IS SEEKING A BOARD CERTIFIED/BOARD ELIGIBLE **OBSTETRICIAN/GYNECOLOGIST** WHO HAS COMPLETED, OR WILL BE COMPLETING, AN APPROVED FELLOWSHIP PROGRAM IN GYNECOLOGY ONCOLOGY, TO FUNCTION AS A TENURE-TRACK FACULTY MEMBER. RESPONSIBILITIES WILL INCLUDE THE TEACHING OF FELLOWS, HOUSE OFFICERS AND MEDICAL STUDENTS, CONDUCTING CLINICAL AND/OR BASIC RESEARCH, AND PATIENT CARE. THE CANDIDATE MUST BE BOARD CERTIFIED/BOARD ELIGIBLE IN GYNECOLOGY ONCOLOGY. SALARY AND ACADEMIC RANK WILL BE COMMENSURATE WITH THE CANDIDATE'S TRAINING AND EXPERIENCE. PLEASE DIRECT INQUIRIES AND CURRICULUM VITAE TO:

JAMES ROBERTS, MD, PROFESSOR AND DIRECTOR
GYNECOLOGY ONCOLOGY DIVISION, OR
PRESTON V. DILTS, JR., MD, PROFESSOR AND CHAIRMAN
UNIVERSITY OF MICHIGAN MEDICAL CENTER
RM L2120, BOX 0270
1500 E. MEDICAL CENTER DRIVE
ANN ARBOR, MICHIGAN 48109-0270

THE UNIVERSITY OF MICHIGAN IS AN EQUAL OPPORTUNITY/AFFIRMATIVE ACTION EMPLOYER. CODE: 53

MATERNAL/ FETAL MEDICINE

OB/GYN PERINATOLOGIST, board certified or eligible, for large perinatal center in San Francisco: Large volume high-risk obstetric service; over 3,000 deliveries/year; Genetic Amniocentesis program; 4 year residency program in Ob/Gyn; 16 staff obstetricians in large multispecialty group; excellent opportunity for clinical practice and research; academic appointment available. Excellent starting salary and fringe benefits.

Send inquiry and C.V. to:

Ira Golditch, M.D.
Chief, Department of Ob-Gyn

Modified retropubic cystourethropexy

John A. Goodno, Jr., M.D., and Thomas W. Powers, M.D.
Arcadia, California

A variation of retropubic suspension of the urethrovesical junction was performed on 26 patients with urinary stress incontinence. Access to the retropubic space was through a low transverse muscle-splitting incision. Surgical technique consisted of securing a helical Prolene suture in the paraurethral fascia at each side of the bladder neck. Each suture was then passed through the abdominal wall fascia, exiting just above the symphysis pubis on either side of the midline, and tied to the opposite suture above the rectus fascia. The desired amount of elevation of the vesical neck was gauged by a Q-tip applicator inserted into the urethra just before the Prolene sutures were tied down. A cystotomy was performed to rule out any inadvertent penetration of the bladder by the nonabsorbable suture material, and the bladder was drained suprapubicly. The small number of cases and short follow-up times do not allow conclusions to be drawn at this time, but results to date have been encouraging. (Am J Obstet Gynecol 1986;154:1211-6.)

Key words: Urinary stress incontinence, cystourethropexy, retropubic

In our practice we were not satisfied with standard abdominal operations for urinary stress incontinence, as detailed in the recent excellent review article by Richardson and Ostergard.[1] We therefore began to study and evaluate alternative approaches. Noting that the modified Pereyra procedure[2] employed a *helical* nonabsorbable suture in the puboeurethral ligament to suspend the bladder neck to the rectus fascia, we developed a transabdominal modification for those patients in whom the abdominal route is preferred.

The concept of suspending the vesical neck from the rectus fascia is not new,[3] but the use of the helical suture in the paraurethral fascia represents an important modification, in our opinion.

We review the surgical technique and short-term results in 26 patients who underwent surgery between December, 1982, and April, 1985.

Material and methods

Patients ranged in age from 27 to 72 years. Preoperative assessment was primarily by history and physical examination. The history was detailed to rule out urgency incontinence, frequent small voidings, and nocturia, which would indicate bladder instability or a possible neurogenic bladder. Pelvic examination to determine the extent of rotational descent of the bladder neck, the hormonal status of the vaginal epithelium, the tone of the levator musculature, and neurologic status was performed.

From the Department of Obstetrics and Gynecology, Methodist Hospital of Southern California.
Presented at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.
Reprint requests: John A. Goodno, Jr., M.D., 622 W. Duarte Rd., No. 202, Arcadia, CA 91006.

A catheterized urine specimen for residual and microscopic urinalysis was obtained. If residual urine volume was above 60 ml, urethrocystoscopic and urodynamic studies, including urethral calibration, were performed.

A preoperative stress test was performed when there was doubt as to the patient's history of urinary stress incontinence. If we were convinced of a valid history, together with supportive anatomic findings, an occasional patient in whom the stress test was negative underwent retropubic cystourethropexy. In this regard we are inclined to agree with Robertson (Robertson JR, M.D., personal communication, July, 1984) that some patients, under the tension of an office test, may artificially inhibit demonstrable urinary leakage by contracting all pelvic musculature.

Of the 26 patients, nine had preoperative urethrocystoscopic studies. Patients with stress urinary incontinence in whom there were indications for vaginal surgery were not included in this study. In some cases the final choice of operative route was not made until after the examination with the patient under anesthesia. The "Q-tip test"[4] often helped to gauge the degree of rotational descent of the vesical neck. There were no cases of secondary urinary incontinence in this study. Hysterectomy was performed in 20 of the 26 patients for coexisting indication.

All patients received 2 gm of Mefoxin intravenously 1 hour prior to surgery, and 2 gm of Mefoxin was given in the recovery room.

At surgery the patient was placed in the "frog leg" position so that the surgeon could insert two fingers into the vagina and elevate the paraurethral tissues during suture placement. A No. 22 Silastic Foley catheter was inserted into the bladder and inflated with 20 ml of water. Access to the operative area was generally

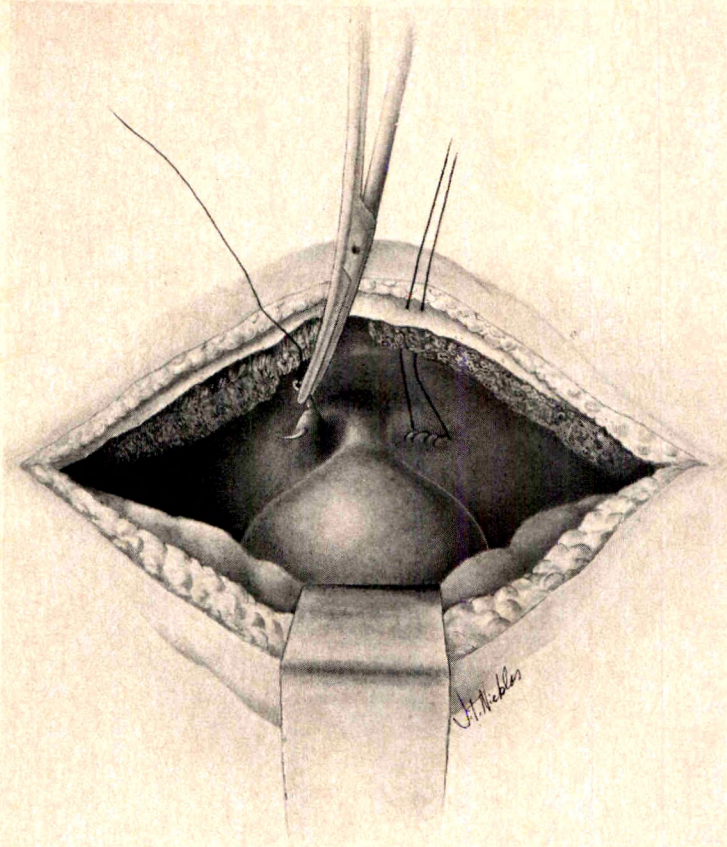

Fig. 1. Illustration of placement of helical suture.

through a Maylard incision, since we believe that the transverse muscle-splitting incision provides much better exposure to the retropubic space.

The paraurethral fatty tissue was bluntly dissected away, and a Babcock clamp was placed on the urethra just below the vesicourethral junction. Prior to placement of the paraurethral sutures, one ampule of indigo carmine dye was given intravenously. One helical Prolene suture was then placed on each side of the urethrovesical junction just inferolateral to the bladder neck. Four or five "bites" were taken through the full thickness of the paraurethral fascia. The axis of the helical suture was perpendicular to that of the urethra. The most medial "bite" of the suture was placed no closer inward than 1 cm from the urethra (Fig. 1).

The bladder dome was then opened by means of a small transverse incision, and the transurethral Foley catheter was removed from below. The bladder was inspected for any inadvertent suture penetration, and the urethral orifices and vesicourethral junction were examined. Traction was placed on the suspensory sutures at this point to assess the effectiveness of their placement. The two ends of each suture were then threaded through a large Mayo needle and passed through the rectus muscle and fascia about 1 to 2 cm above the pubic symphysis and 2 cm lateral to the midline on each side. A No. 14 Silastic Foley catheter was then brought into the retropubic space through a stab incision in the abdominal wall just below the skin incision and inserted into the bladder through the aforementioned cystotomy incision. The bladder was closed with two layers of 00 chromic catgut suture. The retropubic space was drained by a Jackson-Pratt suction drain exiting through a second stab incision just inferior to the abdominal incision but on the opposite side of the suprapubic catheter.

After the rectus fascia was closed, a sterile, lubricated Q-tip applicator was inserted into the urethra and the Prolene sutures were tied to each other over the rectus fascia. The degree to which the bladder neck was elevated was judged by the urethral axis. A urethral axis of 15 to 20 degrees below the horizontal axis was considered optimal in performing this step.

Postoperatively the suprapubic catheter was connected to gravity drainage for 48 to 72 hours. The patient was then allowed to plug the catheter, permitting the bladder to fill, and to attempt voiding if possible. Residual urine volumes were measured after each voiding or voiding attempt. When the urine residual was less than 2 to 3 ounces, the suprapubic catheter was removed.

Patients were generally discharged on the fifth post-

operative day. Those patients who were not voiding satisfactorily by this time were discharged with the suprapubic catheter and instructed to call us when the residual urine volume was less than 3 ounces. At this time they returned to the office for catheter removal. Urinary antibacterial agents were prescribed as long as the catheter remained in the bladder. The earliest a patient voided satisfactorily was the fourth postoperative day, and the longest voiding time was 15 days. The average voiding time was 7.5 days. The retropubic drain was removed on the third or fourth postoperative day because serosanguineous drainage was minimal by this time.

Analysis of results. Follow-up time in the group of 26 patients ranged from 4 months to 29 months postoperatively. No major complications were encountered. An occasional patient experienced dysuria and pyuria, which responded to appropriate antibacterial agents. Transient hematuria was frequently encountered, and the suprapubic catheter was irrigated with small quantities of sterile saline solution as necessary. As mentioned previously, the average number of days of postoperative bladder catheterization was 7.5 days, with a maximum of 15 days.

There were no cases of persistent or recurrent stress urinary incontinence during the follow-up period. Of the 26 patients who had both stress and urge incontinence prior to the surgery, three still reported urgency incontinence postoperatively. To date, postoperative evaluations with the "Q-tip test" have revealed excellent elevation of the previously sagging vesical neck, and there have been no cases of overcorrection with the resultant bladder outlet obstruction.

Comment

There are three salient features in our modification of the retropubic cystourethropexy. First, we used a helical monofilament nonabsorbable suture to obtain a more lasting and more secure purchase of the paraurethral fascia placed exactly at the urethrovesical junction. Stamey,[5] in his discussion of endoscopic suspension of the vesical neck, emphasizes the importance of suspending the fascia exactly at the vesical neck and avoiding suturing distally along the urethra, which may pull up the urethral meatus and flatten the urethra. Additionally, Pereyra and Lebherz[6] point out the ability of the helical suture to produce a ruffling, thickening, and pleating of the paraurethral tissues in order to prevent the suspensory sutures from pulling out at a later date.

Second, we believe that cystotomy is an important step, not only to rule out inadvertent penetration of the bladder by the nonabsorbable suture, but also to further assess accuracy of suture placement at the vesical neck. Although opening of the bladder sounds time-consuming to those not accustomed to this practice, it is simple and adds no more than 5 minutes to the operating time for the procedure.

Third, as a guideline for the extent of cystourethropexy, we believe that the amount of elevation of the vesical neck should be measured by some means in order to prevent undercorrection or overcorrection. Therefore we have employed a Q-tip applicator inserted into the urethra as a gauge to measure the urethral axis while the Prolene sutures are tied over the rectus fascia.

Regarding the preoperative workup, we are inclined to agree with Langmade and Oliver[7] that if the history does not indicate an urgency component to the incontinence, elaborate urodynamic studies are of confirmatory value only. In our study, urethrocystoscopy and urodynamic studies were performed only when there was a question of bladder instability or other urologic problems.

We have found suprapubic bladder drainage more comfortable for the patient, and it eliminates any guesswork regarding the time for catheter removal. Patients received printed instructions regarding catheter care in advance, as well as an informed discussion preoperatively. When patients were voiding consistently, with less than 3 ounces of residual urine, the suprapubic catheter was removed. Using this guideline, we have never had to reinsert a catheter.

Our use of the rectus muscle fascia, rather than the periosteum of the symphysis pubis or Cooper's ligaments, to suspend the bladder neck was motivated by the work of Pereyra and Lebherz[6] and Stamey,[5] who demonstrated the effectiveness of this type of suspensory suture. When operating vaginally for stress incontinence, we have employed the modified Pereyra procedure with gratifying results.

We agree with Mattingly and Davis[8] that patients must be followed up postoperatively for a minimum of 2 years to adequately evaluate the effectiveness of a surgical procedure performed for urinary stress incontinence. Since the average period of postoperative follow-up time in our study was 10 months, we are unable to draw conclusions as to the effectiveness of this technique, but we are encouraged by the results to date. We plan to continue to employ and study this technique when surgery by the abdominal route is indicated.

In an excellent review of stress incontinence in women, Graber[9] stated that at least 50 operations have been described for this condition. We have utilized many of the concepts previously worked out by others in developing our modifications of the abdominal cystourethropexy. The fact that so many surgical procedures have been devised for urinary stress incontinence seems to indicate that none is entirely without problems and that surgeons constantly need to reevaluate and modify their approach as new information and technology are forthcoming.

Discussion

Dr. David Pent, Phoenix, Arizona. Dr. Jack Robertson, a pioneer in reawakening our interest in female urologic problems, once counted 135 surgical procedures for the correction of anatomic stress incontinence (Robertson, J. R., M.D., personal communication). It brings to mind the story of the professor of sociology who, in lecturing to his class on intercourse, announces that there are 93 different positions for having intercourse. He says that the first one is with the woman lying on her back and the man lying on top of her, facing her, at which point a French student in the back of the room says, "Ooh-la-la 94." In that sense, after hearing the presentation by Dr. Goodno and Dr. Powers, I guess we should say, "Ooh-la-la 136." Do we really need to have one more surgical procedure for correcting stress incontinence described? I think that the answer is yes, and the reason is that we are still ignorant and confused in our diagnosis and management of stress incontinence. Therefore every potential worthwhile contribution needs to be listened to, tried, and evaluated. Our specialty has failed to reach a consensus concerning the preoperative evaluation, the intraoperative surgical approach, or the postoperative evaluation. Preoperatively there are those who believe that every patient should have urodynamic testing and others who believe that the diagnosis can be made on clinical grounds, with urodynamic testing being reserved for a small subgroup. Intraoperatively there are those who believe that the successful cure of the problem is dependent on an abdominal procedure, and there are those who are equally vehement in insisting that restoration of the anatomy can be achieved only by the vaginal approach. Postoperatively we cannot even agree on what constitutes a cure, some authors accepting marked improvement in symptoms as evidence of a successful repair and others subjecting their patients to electronic monitoring to determine the loss of even small amounts of urine. This lack of agreement on what even constitutes a cure is one facet of the larger problem, in that although individual authors have tried to classify the degrees of incontinence, there is no generally accepted method of classification. Rational treatment has to be based on some system that takes into account the patient's age, her menopausal status, her weight and degree of obesity, her parity (or, in this age of cesarean sections, the number of vaginal deliveries might be a more valuable statistic), and, of course, the objective anatomic findings with regard to the urinary tract.

There is little, considering the 130-odd procedures already described, that is genuinely new in the surgical correction of stress incontinence, but Dr. Goodno and Dr. Powers are to be complimented on selecting certain features and bringing them together in one procedure. They have used the helical monofilament, nonabsorbable suture of the Pereyra procedure to solve the problem of the suture's tearing through attenuated fascia, which is thought to be the cause of many of the failed abdominal procedures. Other authors have addressed the problem in varying ways, such as putting in a series of sutures above the urethrovesical junction to help take some of the strain off the urethrovesical suture at the time of increased intra-abdominal pressure. Dr. Goodno and Dr. Powers also utilize a cystotomy to rule out the placement of the nonabsorbable sutures through the bladder mucosa and to allow confirmation of the effectiveness of the suture placement. Their Maylard incision affords excellent exposure, and obviously the better the exposure, the easier the procedure and the higher the success rate. Finally, the use of some objective form of measurement, in this case elevating the urethral axis to 15 to 20 degrees above the horizontal, has helped to avoid both overcorrection and undercorrection. As the article states, the number of patients is small, follow-up is short, and, in addition, we must remember that every new procedure, when initially reported, has a high success rate in the hands of its developer. Only when the procedure falls into the hands of the rest of us can we more accurately determine its true success rate.

Two questions come to mind. First, it was stated that this procedure was selected "for those patients in whom the abdominal route is preferred." In light of the encouraging results, has consideration been given to performing whatever vaginal procedures are indicated but forsaking the anterior colporrhaphy in favor of this new modified retropubic cystourethropexy? Second, a thoughtful observer of the incontinence problem, Edward McGuire, a urologist, writes that in 8 years of Bonney-Marshall testing, he has found only two women in whom urethral urinary loss could not be stopped by the maneuver. He goes on to state that the best position for the Bonney-Marshall test is with the patient in the upright position and notes that "objective examination of a standing patient by a crawling physician is difficult.

I personally resort to this unpleasant routine when a postoperative patient complains that she is still wet. I am uncertain as to whether this is the case because I feel guilty or vengeful. In any event, the practice is unsatisfactory in relieving either emotional state, usually serving only to amuse the nursing staff."[1]

In addition, Bhatia and Bergman,[2] using urodynamic measurements, have shown that the Bonney-Marshall stress test restores continence by causing extrinsic compression of the urethra and urethrovesical junction, and therefore the test cannot be relied on as a prognostic screening procedure. Indeed, Dr. Goodno and Dr. Powers report that there were patients in their series in whom the stress test was negative but in whom they did the cystourethropexy because they were "convinced of a valid history together with supportive anatomic findings." Does Dr. Goodno believe in the prognostic value of the stress test?

Dr. Solon Barbis, Sacramento, California. It seems that this procedure is formidable. What is the average length of operating time required to complete this operation?

Dr. Duncan Neilson, Portland, Oregon. I am interested in the semiquantitative measurement of the urethral angle with the use of the Q-tip to determine the final position of the bladder. The question I have is, Does the position of the legs affect this measurement? I gather that these patients were in the frog-leg position during the procedure, but if stirrups are used or a different position is used, is that angle measurement the same?

Dr. Goodno (Closing). Thank you, Dr. Pent, for your humorous and informative discussion and some very good points as to the variety of surgical procedures. In answer to the question about whether we do some procedures vaginally, generally we treated those patients who had obvious genital prolapse and big cystoceles from below, and we used the Pereyra procedure in those cases. The patients whom we treated had anatomic incontinence, but they did not have the marked prolapses some of those slides showed. In regard to the Marshall-Marchetti test, I don't think that it's greatly reliable—or prognostically valuable, either—and I think that Jack Robertson has suggested that perhaps we give women a couple of Pyridium tablets, have them wear a minipad around for a few hours, and then report back to us on the amount of staining of their perineal pad. We're considering doing this, both preoperatively and postoperatively, to objectively assess urinary incontinence.

Dr. Hibbard has commented about opening the bladder and inserting a finger in the urethra. We have done that from above. We've put our finger right down through the vesical neck, and it's surprising how often we find a patulous vesical neck. Then, although we haven't placed a suture doing that, we have then pulled up on the suture we have already placed to see how well it elevates the vesical neck.

As far as the formidability of the operation—it really isn't. It's very simple—opening and closing the bladder takes about 5 minutes. The entire procedure takes an hour or less. In answer to the question of whether the position of the legs affects the Q-tip test, we always have the table parallel to the floor when we measure that. As far as the patient's being in a frog-leg position or in stirrups, I haven't observed any great change.

Tubal conservation in ectopic pregnancy: A study of 200 cases

Jack G. Hallatt, M.D.
Los Angeles, California

There have been 1152 cases of ectopic pregnancy at Kaiser Permanente Hospital from 1953 to 1980. In 200 cases the involved tube was preserved with no surgical complications. There have been 122 subsequent pregnancies, 24 of which were repeat ectopic pregnancies. Twelve were in the involved tube and 12 were in the opposite tube, demonstrating conclusively that both tubes are at equal risk of ectopic pregnancy. Conserving the involved tube does not increase the incidence of ectopic pregnancy but does increase the chances for intrauterine pregnancy in this subfertile population. (Am J Obstet Gynecol 1986;154:1216-21.)

Key words: Pregnancy, ectopic; tubal conservation

The lethal nature of hemorrhage from ruptured ectopic pregnancy was reported in 1876 by Parry and Lea.[1] This series of 529 cases, with a mortality rate of 69%, prompted Lawson Tait,[2] the "father" of gynecologic surgery, to recommend salpingectomy as an emergency life-saving procedure in the treatment of ectopic pregnancy. He reported 38 cases in 1888, with only two maternal deaths. Complete salpingectomy, as soon as the diagnosis is made, has continued to be the conventional management of tubal pregnancy for the past 100 years.

About 15% of patients with ectopic pregnancy will have a repeat ectopic pregnancy in the residual tube, and removal of that tube results in sterility. Many of these patients requested that the tube be conserved to preserve their fertility. These cases have demonstrated the feasibility and safety of tubal conservation.

Important to an understanding of ectopic pregnancy and relevant to conservation of the involved tube is a classic report from Helsinki, Finland, in 1955, by J. J. Lund.[3] The report is summarized in Table I and reveals the natural history of ectopic pregnancy. Three hundred eighty-seven hospital admissions for ectopic pregnancy were studied. Fifty-five percent of the patients were observed to have subacute ectopic pregnancies. Forty-two percent of these patients had a recurrent hemorrhage, demonstrating the episodic nature of ectopic pregnancy, and required emergency operation. One third of the entire series had no further symptoms.

Total patients admitted with ectopic gestation	387	
Acute, requiring operation	167	(45%)
Subacute, patient observed	220	(55%)
Later required operation	92	(42%)
Medically resolved	128	(33%)

Table II. Summary of subsequent pregnancies up to menopause after ectopic pregnancy, reported by Lund, Helsinki, Finland, 1955

Treatment	*Intrauterine (%)*	*Repeat ectopic (%)*
Surgically treated (tube removed)	45	16
Medically treated (tube conserved)	45	15

Their pregnancy tests became negative, their masses resolved, and after averaging more than a month in the hospital, they were discharged. All patients were followed up through the menopause. Subsequent pregnancies are shown in Table II. Forty-five percent of both patients with and without operation had intrauterine pregnancies. Sixteen percent of the group with operation and 15% of the group without operation had repeat ectopic pregnancies. The cases without operation represent conservation of the involved tube.

Table III is a compilation of cases of tubal conservation in 1967, which shows that tubal patency is maintained and fertility is preserved after tubal conservation. Subsequent pregnancies were predominantly intrauterine. The repeat ectopic pregnancy rate was 15%, which was the same as that reported by Lund. Preservation of the involved tube in ectopic pregnancy is

now regarded as an acceptable procedure and should be considered when fertility is desired by the patient. The purpose of this paper is to analyze the results of conserving the involved tube in 200 cases of ectopic pregnancy at the Kaiser Permanente Hospital in Los Angeles from 1953 to 1980.

Material and results

The Kaiser Permanente Hospital in Los Angeles provides prepaid comprehensive medical and surgical care for a representative cross section of the Southern California population. Ectopic pregnancy is managed by the entire staff of the Department of Obstetrics and Gynecology as an emergency surgical condition. The surgical procedure is determined by the personal preference of the staff person on duty. Some of the staff are reluctant to conserve a tube damaged by ectopic pregnancy. Those with a special interest in fertility are more likely to conserve the involved tube. Some of the staff will base their decision on the results of a tubal patency test at the time of operation or on the gross appearance of the contralateral tube.

Since the hospital opened, in 1953, until 1980, there have been 1152 cases of ectopic pregnancy requiring operation. In 200 cases or 17%, the involved tube was not removed. These 200 cases are felt to be representative of the entire series, as the location of the ectopic gestation was essentially the same as in the cases with salpingectomy, as shown in Table IV. Fifteen percent were in the proximal one third of the tube, 28% were in the middle one third, and 57% were in the outer one third of the tube. Subsequent pregnancies are shown in Table V. In 26 cases, the involved tube was the only tube and fertility was more compromised than in the patients with two tubes. While the numbers are too small to be statistically significant, pregnancies after involvement of the inner one third of the tube were almost as likely to be ectopic as intrauterine. Pregnancies after an involvement of the middle and outer portions of the tube were four times as likely to be uterine as ectopic. There were no surgical complications in the 200 cases and no patient required further surgical procedure to control bleeding. There were, however, many cases where tubal conservation was attempted, but operation terminated in a salpingectomy to control persistent bleeding. No special techniques or departures from standard gynecologic surgical procedures were used in any of the cases.

There has been a significant change in the findings in ectopic pregnancy in the last few years, as shown in Table VI. The findings in the 1152 cases are compared with those in the 226 cases occurring in the 3 years from 1980 to 1983. There has been a doubling in incidence of ectopic pregnancy in terms of deliveries. Ectopic pregnancy is occurring at a younger age. There are now twice as many cases after tubal surgery as before. Twelve percent of all ectopic gestations are now associated with the use of an intrauterine contraceptive device. This figure is directly related to the number of women using the intrauterine contraceptive device for

Table VI. Tubal conservation in ectopic pregnancy: Current changes in findings in ectopic pregnancy

	1953-1980	*1980-1983*

contraception. Table VII lists some of the factors that lead to an early diagnosis and enhance conservative management. The use of the very sensitive and specific β-subunit of human chorionic gonadotropin pregnancy test as a screening procedure in all high-risk patients identifies candidates for ultrasound and laparoscopy to aid in the diagnosis before rupture occurs. In the last 3 years, ultrasound was used in 23% and laparoscopy was used in 18% of all ectopic gestations. That the diagnosis is now being made early is documented by the finding of no hemoperitoneum in 15% of all ectopic pregnancies. The involved tube is now conserved in 26% of all ectopic gestations. Follow-up of 72% of these 200 cases indicates that future fertility favors uterine pregnancy over repeat ectopic pregnancy in both the involved tube and in the contralateral tube. Eighty percent of subsequent pregnancies were uterine pregnancies, and 20% were repeat ectopic pregnancies. It is significant that of the 24 repeat ectopic gestations, one half were in the involved tube and one half were in the contralateral tube. This follow-up is a crude evaluation of fertility, since the number of patients using contraception and not desiring or attempting pregnancy was not determined. Of the 1152 patients with ectopic pregnancy, 20% were infertile before the ectopic pregnancy.

Comment

The cause of ectopic pregnancy is chronic damage to the endosalpinx by prior infection or operation. There is fusion of the plicae of the endosalpinx, creating pockets that entrap the passively migrating zygote. On the sixth day after fertilization, the blastocyst will implant by trophoblastic invasion of adjacent maternal tissue. In the uterus, the maternal blood vessels are protected by decidua. In the tube, there is no decidua to protect the maternal blood vessels, so hemorrhage occurs very early in the pregnancy. Aggressive implantation and trophoblastic invasion and hemorrhage can continue for 12 weeks as long as there are viable villi. The damage to the tube from hemorrhage and extravasation appears to be much more destructive to the tube than it actually is. The damage is repaired physiologically by absorption of blood and regeneration of the endosalpinx, restoring tubal patency. This has been repeatedly observed at subsequent operation, where the involved tube is found to be anatomically normal. The anatomy is also restored by tubal peristalsis and ciliary action, whether the tubal defect is closed surgically or left open, as advocated by Pendleton Tompkins.[4] The dynamic physiology of the fallopian tube is as responsible for the success of tubal conservation as is the surgical procedure.

It is still too early to evaluate the role of atraumatic operation in ectopic pregnancy, but the preliminary reports do indicate a higher intrauterine pregnancy rate and a lower repeat ectopic pregnancy rate.[5-7] The inherent fact of ectopic pregnancy is that both tubes are in equal jeopardy of recurrent ectopic pregnancy. This is due to damage from a prior infection that involved the entire tube and that cannot be repaired surgically. The patient can be told that should she become pregnant, the pregnancy is more than four times as likely to be in the uterus as it is to be in the tube.

There have been several reports[8] of recurrent hemorrhage requiring operation after salpingostomy or the procedure of "milking" the pregnancy out the fimbriated end of the tube. If viable villi are left in the tube, then a subsequent hemorrhage may occur. The average gestational age of an ectopic pregnancy at operation is 6 weeks. The products of conception can be overlooked or obscured by the hemorrhage and blood clots. If one is not certain that the entire pregnancy has been enucleated, then one should evaluate the patient with serial determinations of the β-subunit of human chorionic gonadotropin which should decrease to negative in 2 weeks[9] unless viable villi persist or a second pregnancy is present.

If inspection of the ovaries reveals more than one corpus luteum of pregnancy, then one can expect to find another pregnancy, which may be intrauterine or ectopic.

While ultrasound is now used in 23% of all ectopic pregnancies, its greatest value is in identifying an intrauterine pregnancy, thus ruling out an ectopic pregnancy, except for the rare case of combined pregnancy. The ectopic gestation itself is rarely identified by ul-

trasound since the gestation is usually too early and is frequently distorted by hemorrhage disrupting the gestational sac.

Laparoscopy has replaced the diagnostic laparotomy in the diagnosis of ectopic pregnancy. The early unruptured ectopic pregnancy without hemoperitoneum can be diagnosed only by laparoscopy or laparotomy. These patients are ideal candidates for tubal conservation as they are stable and the tubal anatomy is not excessively distorted by hemorrhage and rupture.

Salpingostomy is best performed by using the unipolar cutting current to incise the tube and expose the implantation site. The gestational sac is enucleated by blunt dissection and bleeding points are cauterized with the bipolar thumb forceps. It is usually necessary to ligate the tubal artery that parallels the tube in the mesenteric border proximal and distal to the pregnancy. Bleeding points are best identified by irrigation with lactated Ringer's solution. The serosa is approximated with fine polyglycolic or polyglactic sutures as any raw area will result in adhesions. If bleeding cannot be controlled, then resection of the involved segment, rather than salpingectomy, is indicated to conserve the tube. This permits the possibility of later reanastomosis if indicated and desired. Should the patient not desire further pregnancies, then removal of only the involved portion of the tube is indicated. Partial salpingectomy does not increase the incidence of ectopic pregnancy.

The fertility of the patient with ectopic pregnancy is compromised, and the removal of the involved tube may further diminish her fertility. This study shows that the involved tube can be safely conserved and that subsequent pregnancies are predominantly uterine. It is logical to assume that two tubes favoring uterine pregnancy are better than one tube to enhance fertility. It is therefore recommended that the involved tube in ectopic pregnancy be conserved in the patient who desires a successful pregnancy.

Discussion

Dr. Arthur M. McCausland, Sacramento, California. This article by Dr. Hallatt has great clinical significance, especially today.

In the past, the difficulty was just in making the diagnosis of an ectopic pregnancy before it ruptured. Today the problem is how to manage an ectopic pregnancy diagnosed at a very early stage. Our ability to diagnose an early tubal gestation through the use of the β-subunit of human chorionic gonadotropin, ultrasound, and laparoscopy has given us the option of a more conservative approach. This approach raises new questions.

First, does conserving the involved tube increase the risk of a repeat ectopic gestation, and second, does it enhance the chance for a future intrauterine pregnancy? Dr. Hallatt addressed these questions and has found that a conservative approach gives the best overall results.

A review of the world's literature confirms these findings. Schenker[1] reviewed 24 articles addressing similar questions. He also concluded that tubal conservation increases the number of future intrauterine pregnancies and does not increase the risk of repeat ectopic pregnancies in the involved tube over the contralateral tube.

Another statistic presented in Dr. Hallatt's paper was that if an ectopic pregnancy was found in the inner one third of the tube, the next pregnancy was as likely to be a repeat ectopic pregnancy as an intrauterine pregnancy. This 50% rate of repeat ectopic gestation is in contrast to a 15% repeat rate if the original ectopic pregnancy was found in the middle or distal portion of the tube. This is interesting because in my study[2, 3] of ectopic gestations following tubal injury, it was found that the proximal portion of the oviduct responds differently to injury than does the middle or distal portion of the tube. Tubal activation instead of fibrosis is seen in the proximal segment after injury, whether from operation or infection. This is why salpingitis isthmica nodosa is usually seen only in the proximal oviduct although the entire tube is usually infected. Therefore, the pathologic process causing partial tubal occlusion in the proximal oviduct might be expected to be more extensive than in the middle and distal portions. This could explain why ectopic pregnancy recurs more often in the proximal oviduct.

Dr. Hallatt mentioned that in Finland a significant number of patients with ectopic pregnancies were observed without operation. This nonsurgical management awaiting a tubal abortion was fascinating to me. Evidently, the same approach has been used in China. I do not know whether to call this treatment radical or conservative but I guess if a patient is lucky enough to spontaneously abort the ectopic pregnancy out the end of the tube without operation, the ultimate in tubal conservation has occurred. However, the hospital uti-

lization review committee may not understand the weeks of prolonged hospitalization.

In one case, a woman had an intrauterine contraceptive device and her menstrual period was late. The human chorionic gonadotropin was positive 6600. Her husband, an outstanding radiologist, found on ultrasound examination a 3 to 4 cm complex left adnexal mass and no intrauterine pregnancy. Since she was asymptomatic, he wanted me to follow up with serial human chorionic gonadotropin, hemoglobin, and daily ultrasound evaluations. Reluctantly I agreed and within 3 days, the adnexal mass disappeared. Cul-de-sac fluid was then present and subsequently resorbed. The hemoglobin was stable and the human chorionic gonadotropin dropped to zero. I cannot recommend this treatment but it certainly was thought-provoking.

I enjoyed reviewing Dr. Hallatt's article and have only two questions. First, was salpingostomy the only type of conservative operation done? Were any manual tubal abortions or segmental resections with anastomosis performed? Second, since there is a 50% rate of repeat ectopic gestation when the original one involves the proximal oviduct, should a salpingectomy be considered over a conservative approach in this situation, especially if the contralateral tube and ovary appear normal?

DR. LEROY CASPERSEN, Portland, Oregon. Dr. Hallatt, how many patients underwent reoperation because of persistence of pregnancy symptoms or bleeding?

We have been performing salpingostomy, when feasible, for some time but have had three or four cases where we found it necessary to reoperate because of failure to remove all the gestational tissue.

DR. CLIFFORD CURTIS, Redwood City, California. During a 6-month period I personally managed six cases of tubal pregnancy; four patients were able to achieve a term pregnancy subsequent to conservative management and two of the patients, specifically Cases 4 and 6, had the misfortune of having two consecutive ectopic gestations. In Case 4 a salpingectomy was performed 5 months before I examined her. The pregnancy was in the infundibulum and was expelled at operation. She again became pregnant 5 months later and the pregnancy went to term. In Case 6, the first ectopic gestation was managed by a linear salpingotomy. Nine months later she had another ectopic pregnancy that was expelled. Eight months later she became pregnant again and this pregnancy went to term. We had, as has been mentioned, a bad local experience with hemorrhage and persistence of ectopic gestation after exploratory laparotomy at our hospital and, corroborated by the literature, decided that we had to do something else. Now fairly routinely, when we perform a salpingotomy or salpingostomy, we will ligate the mesosalpinx and put sutures through each of the arcades that are available. In the last 2 years, no doctor in our hospital has had to reoperate to repair a bleeding tube or remove a persistent ectopic trophoblast.

DR. JOHN MOLITOR, Fullerton, California. I am the chairman of the Bio-Ethics Committee at the Catholic Hospital at which I work. We have a new dilemma now with tubal pregnancies. Salpingectomy has been viewed as removal of an abnormal organ, and the termination of the pregnancy then was a "secondary, unintended effect," or the so-called principle of double effect. Some people now view salpingotomy as a direct attack on the fetus, which is, of course, morally illicit, according to church doctrines.

I feel that in most of these cases the fetus is already dead, even in the very early cases, even perhaps with no hemoperitoneum due to abruptio placentae.

My question for Dr. Hallatt is based on his broad experience with tubal pregnancy. How does he feel about the viability of the fetus at the time of salpingotomy? If most of them are already dead, then we have resolved our dilemma. If not, then we still have to face it.

DR. HALLETT (Closing). In answer to Dr. McCausland's question regarding whether salpingostomy was the only procedure in conserving the tube, actually, nature has done the salpingostomy, or salpingotomy, on the majority of these patients, and all we had to do was try to repair the damage. Fortunately, the dynamic nature of the tube is such that it repairs the damage that has been done. We must atraumatically accomplish hemostasis and approximate serosa to serosa, minimizing as much raw area as possible. The tube will reanastomose and reconstitute itself. It has been demonstrated that the endosalpinx can regenerate and span an area of 1 inch.

The second question was why ectopic gestations recur more frequently in the proximal portion of the tube. The proximal portion of the tube is different anatomically and physiologically from the outer two thirds of the tube. Whether one should remove it because of a 50% chance of recurrent ectopic gestation is a consideration. Many patients would desire a 50% chance of an intrauterine pregnancy. This compares favorably with that of in vitro fertilization, so I would conserve the tube. I hope to be able to accumulate enough cases to document this fact statistically.

Dr. Caspersen, none of the 200 patients had to undergo reoperation. There was no subsequent hemorrhage. As I mentioned, there have been several reports of subsequent hemorrhage requiring operation because the ectopic gestation was not completely removed.

Dr. Molitor, one third of all embryos are necrotic at the time of operation for ectopic pregnancy. The other two thirds are potentially viable but severely compromised and are destined to "self-destruct." Recurrent hemorrhage is the nature of the disease.

Attempts to transplant the gestational sac into the uterus, by myself and others, have been unsuccessful.

Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention

William M. Petty, M.D., Richard O. Lowy, M.D., and Albert A. Oyama, M.D.
Portland, Oregon

Abdominal hysterectomy after treatment of cervical cancer by radiation therapy is associated with a significant rate of postoperative vesicovaginal fistulas. In this series, five patients with invasive cancer of the cervix treated by radiation therapy developed new cervical or uterine neoplasms 1 to 27 years after treatment. All underwent abdominal hysterectomy without postoperative fistula formation. Success is attributed to cautious surgical technique and to the use of the omental pedicle graft to bring new vascularity to the vaginal apex and bladder base. The technique of forming an omental pedicle graft is described. (AM J OBSTET GYNECOL 1986;154:1222-6.)

Key words: Cervical cancer, radiation therapy, abdominal hysterectomy, omental graft

Uterine sarcomas, endometrial cancer, and other pathologic processes may occur in the retained uterus of a woman previously treated for cervical cancer by radiation therapy. Operative management of these problems is difficult and is associated with a high incidence of postoperative vesicovaginal fistulas. Radical abdominal hysterectomy is associated with a 17% to 53% incidence of postoperative fistulas in several small series.[1-3] Graham and Goplerud[2] report that 3 of 13 patients (23%) developed urinary fistulas after total abdominal hysterectomy. Six additional patients underwent total abdominal hysterectomy with omentopexy, and none of these patients developed fistulas.[2]

Direct attachment of the omentum to the vaginal apex may cause traction on the stomach, thereby giving rise to chronic epigastric discomfort.[4] Operative techniques have been developed to lengthen the omentum while preserving its blood supply.[4,5] These techniques allow a vascular omental pedicle to be brought down to the vaginal apex and bladder base without traction. These techniques are also useful in repairing radiation therapy–related vesicovaginal fistulas.[6,7]

Material and methods

From 1981 to the present time, five patients were treated for new, clinically localized cervical or uterine disease. All had had previous invasive carcinoma of the cervix that had been treated with radiation therapy. The original radiation therapy treatment records were available for four of the five patients. They were re-

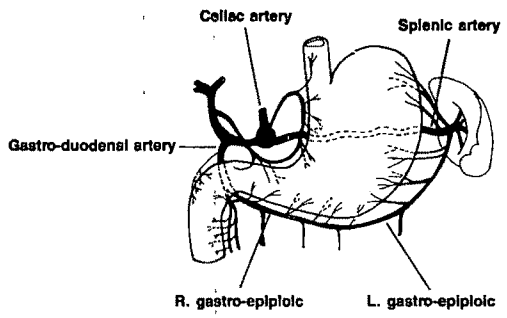

Fig. 1. The omental blood vessels arise from the right and left gastroepiploic arteries. The right gastroepiploic artery originates from the gastroduodenal artery, which comes from the common hepatic artery and ultimately the celiac artery. The left gastroepiploic artery comes from the splenic artery, which is also a branch of the celiac artery.

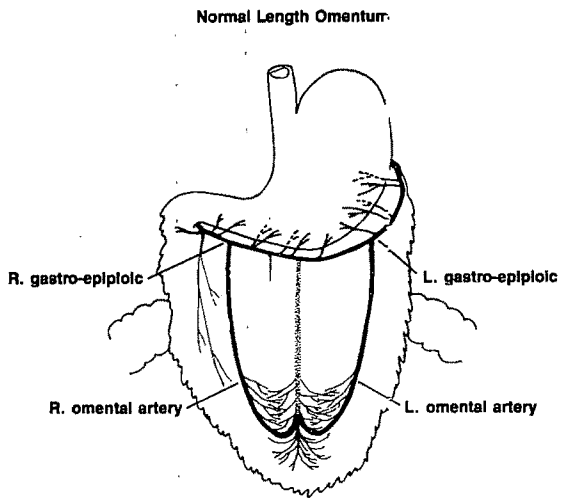

Fig. 2. The omental arteries are, from *left* to *right*, the accessory omental artery, the right omental artery, a variable middle omental artery, and the left omental artery.

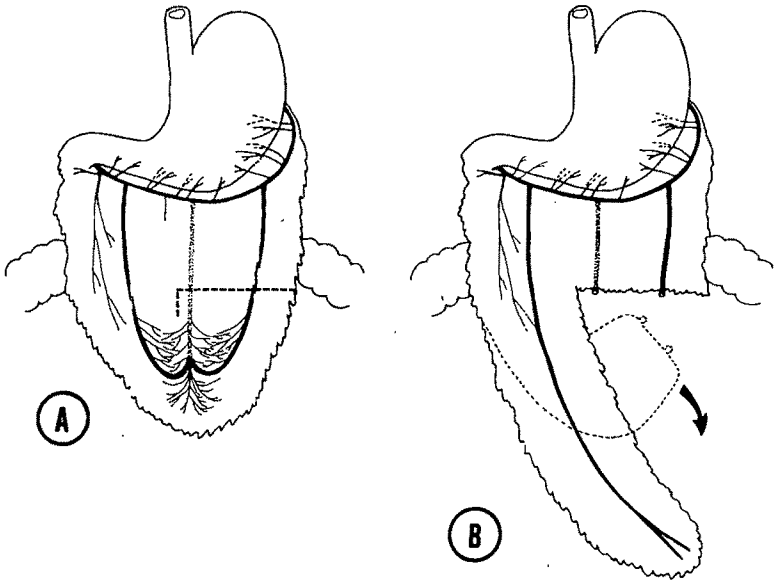

Fig. 3. *A*, The normal-length omentum is lengthened by partially transecting the omentum in reversed J configuration. *B*, This mobilized omentum is unfolded for attachment to the vaginal apex.

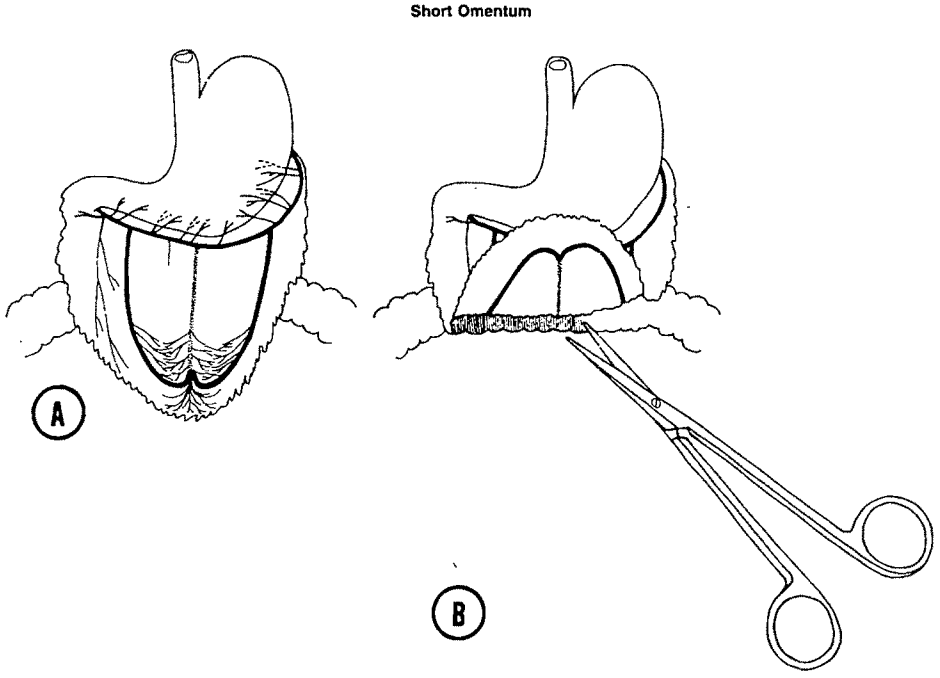

Fig. 4. *A*, Short omentum. *B*, Elevation of omentum exposes peritoneal attachment to transverse colon.

viewed by one of us (R. O. L.) and were found to conform to standard treatment.

In each case the new abnormality differed from the original cervical cancer. Slides of three of the five original and all of the new disease processes were available and were reviewed by one of us (A. A. O.).

Patient clinical characteristics are summarized in Table I. The hospital course and outcome for each patient are summarized in Table II.

All hysterectomies were performed through midline incisions. Appropriate staging procedures were performed, including peritoneal cell washes, lymph node biopsies, and other biopsies. Hysterectomy technique was meticulous in order to prevent bladder injury. Antibiotics, usually a cephalosporin with or without an aminoglycoside, were used prophylactically for 48 hours.

Patient E. M. had an omentum that was long enough

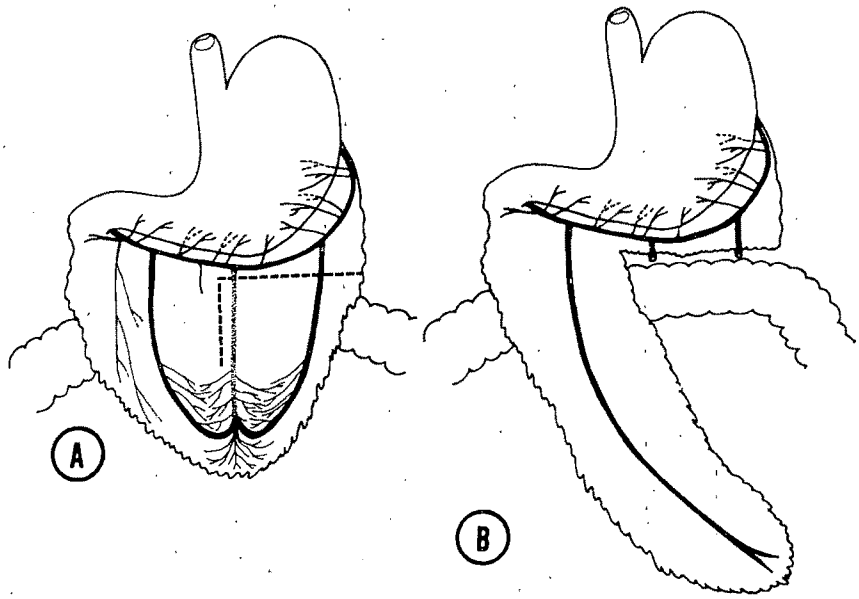

Fig. 5. *A*, Incision of omentum *(dotted lines)*. *B*, Omental pedicle is unfolded.

that its most dependent portion could be sutured to the vaginal apex without tension on it. The other patients had to have omental lengthening so that the omentum could be attached to the vaginal apex.

Omental lengthening by formation of an omental pedicle graft is based on the vascular anatomy of the omentum.[4, 5] The omental blood supply arises from the right and left gastroepiploic arteries, respectively (Fig. 1). The right and left omental arteries provide the main blood supply to the omentum. The right and left omental arteries anastomose with one another through the distal omentum (Fig. 2).

When the omentum appears to be long enough so that a partial transection of the omentum below the transverse colon would give adequate length to reach the vaginal apex, a reversed J-shaped partial transection of the omentum may be performed with the use of absorbable sutures (Fig. 3, *A*). The freed portion may then be rotated downward to be fixed to the vaginal apex with absorbable sutures (Fig. 3, *B*). The right omental artery is usually the largest omental artery. It is preserved by transecting the left side of the omentum and the left omental artery.

When the omentum is short, it must be dissected free from the transverse colon to obtain additional length for the pedicle. The undersurface of the omentum is attached to the anterior surface of the transverse colon by peritoneal adhesions and small blood vessels. This attachment is visualized by lifting up the distal omentum. Adhesions may then be transected and blood vessels ligated (Fig. 4).

The undersurface of the omentum has the greatest degree of freedom from the mesentery of the transverse colon on the left side. It may adhere to the transverse mesocolon on the right side. Dissection of the undersurface of the omentum from the left side usually avoids the need to dissect the omentum from the transverse mesocolon.

The incision down the middle of the omentum should be low enough to unfold the pedicle (Fig. 5). The new distal end of the pedicle is then attached to the vaginal apex by two or three interrupted, absorbable sutures. The pedicle is not sutured to the bladder or to the pelvic sidewall. The pelvic peritoneum is closed from each lateral sidewall to the lateral edge of the omental graft when possible.

Results

The total operating time for each of these patients was long and reflects the time spent carefully performing the hysterectomy. The omental graft adds less than 15 minutes to the procedure.

Four of the five patients had no significant postoperative problems. Patient E. M. delayed hospital discharge an additional 2 days in an attempt to achieve normal voiding and catheter removal. Only Patient M. S. had a complicated recovery. This was due to slow resumption of peristalsis.

When possible, suprapubic catheterization of the bladder was performed to allow prolonged bladder drainage if necessary and to prevent bladder trigone injury. Since the space of Retzius of Patient M. S. was obliterated by fibrosis, transurethral bladder drainage was performed. Patients J. S. and T. H. had arbitrarily long periods of catheterization. Patients A. H., E. M., and M. S. had catheters removed when they were able to void satisfactorily.

Two patients developed their abnormalities 1 year after radiation therapy. Three developed abnormalities late, 14 to 30 years after treatment. Although all patients were thought to have clinically localized disease, two had more advanced disease, found at the time of operation.

Despite the above factors, none of these patients developed any postoperative fistulas. Urinary, bowel, and vaginal tissues have remained intact. These organs have remained as functional as they were before operation was performed.

Comment

Vesicovaginal fistulas after complete pelvic radiotherapy and hysterectomy occur most commonly 5 to 12 weeks postoperatively.[2] This time delay suggests that the fistula may occur from progressive ischemia of the bladder base. The omentum has been used in several anatomic areas for improving tissue vascularity.[4] Improved vascularity to the bladder base and vaginal apex may be the reason that the omental graft may prevent fistula formation.

The length of bladder catheterization of patients in this series was variable. The absolute length of time of catheterization is probably not important. Currently suprapubic catheters are being removed when the patient is able to void without retaining significant amounts of residual urine.

The omentum is often too short to reach the vaginal apex without undue traction. The use of omental lengthening techniques has allowed easy application of the intact omentum to the vaginal apex and bladder base.

Abdominal hysterectomy with omental graft has resulted in no fistulas to date in this series. This outcome parallels the experience of Graham and Goplerud[2] and suggests that the omental pedicle graft may prevent fistula formation in patients undergoing abdominal hysterectomy who have previously received full radiation therapy for cervical cancer.

Discussion

Dr. John J. Stapleton, Reno, Nevada. When Roentgen discovered the x ray 90 years ago, he inaugurated a great service to women with carcinoma of the cervix. Unfortunately, he also bestowed on the gynecologic surgeon who may subsequently operate on these patients a formidable task—adequate surgery without subsequent fistula formation. After the first successful radium implant by Cleaves, in New York City, Forssell established the Radiumhemmet in Stockholm. From this institution, Heymann and, subsequently, Kottmeier dictated the treatment of cervical carcinoma to the entire world for more than half a century. The morbidity and mortality rates for radical surgery initially reported from the clinics of Wertheim and Okabayashi were unacceptable to most gynecologists. It was not until Meigs' definitive work, "Surgical Treatment of Cancer of the Cervix," was published in 1954 that primary surgery for this disease was reborn. This work not only heralded an era of two choices of treatment, but in the effort to effect even better results, various associations of radiation and surgery subsequently emanated forth. Certain combinations resulted in a high incidence of postoperative fistula formation. Unfortunately the type of fistula was not usually amenable to the classic primary closures of Sims, Latzko, Boari-Casati, or Moir but necessitated diversionary surgery. Prevention, rather than repair, became the most important consideration.

I thank Dr. Petty and his colleagues for this excellent descriptive and informative presentation, which demonstrates the employment of omentopexy for prophylaxis against fistula formation when surgery and radiation are combined. Although Walters first described the utilization of the omentum to repair a vesicovaginal fistula in 1937, the major body of work reporting the use of this pedicle of vascular fat is found in the genitourinary literature; renal and ureteral wraps to prevent subsequent leaks are commonly employed. Indeed, until I reviewed the literature to discuss this article, I had no idea of the number and variety of uses for the omentum. My knowledge was limited to removal for malignancy or development of an omental carpet after exenteration.

I have several questions for Dr. Petty. Do you advocate prophylactic omentopexy at the time of primary surgery for those patients who will have or most likely will have postoperative irradiation? Would you recommend an omental graft for primary benign surgery when there is extensive denuding of the pelvic contents but no invasion of the gastrointestinal or genitourinary organs? Would you recommend this procedure even if a significant and noncosmetic extention of the initial incision is required?

I question the preference for suprapubic, as opposed to urethral, drainage. I strive to avoid any unnecessary invasion of the irradiated bladder. Finally, will you comment on pelvic drainage with respect to method and time? This alone may be responsible for the almost twofold increase in fistula formation between Symmonds' series and Graham and Goplerud's first group.

Dr. Petty (Closing). You asked about the prophylactic use of omentopexy in the patient who was to receive postoperative radiation therapy. I have not done that. It would be worthwhile if one were finding the occurrence of many fistulas from this treatment combination. There are many other uses of the omental pedicle graft. I have used it to cover a disrupted appendicele stump in one patient. In another, in whom the vaginal apex sloughed after removal of an infected postpartum uterus, the pedicle graft was an effective barrier for and allowed healing of the open, necrotic vaginal apex. The omental pedicle graft is useful for improving the success rate of repairing large vesicovaginal fistulas. These fistulas are approached abdominally and the pedicle graft is interposed between the repaired bladder and vaginal portions of the fistula. As in the fully irradiated cervix, I have used the pedicle graft in the patient with a partially irradiated cervix, if at the time of hysterectomy the bladder base is found to be thin or the bladder is injured. Finally, the omental pedicle has been used by me for its absorptive capacity. It can keep permanently resolved large abdominal peritoneal or retroperitoneal cysts. The cyst wall is opened, and the graft is inserted and sutured to the opening of the cyst. Other uses of this simple procedure may certainly be developed in gynecologic surgery.

Expanded toxemia syndrome or gestosis

Robert C. Goodlin, M.D.
Denver, Colorado, and Omaha, Nebraska

The expanded toxemia syndrome or gestosis refers to polysymptomatic diseases that are associated with pregnancy. This report discusses those cases without initial hypertension or proteinuria that were "cured" by delivery and were associated with maternal and fetal morbidity (usually intrauterine growth retardation). A list of suggested tests is presented to document gestosis in pregnant women with medical illnesses. Unlike preeclampsia, gestosis may occur at almost any time in pregnancy. (AM J OBSTET GYNECOL 1986;154:1227-33.)

Key words: Toxemia, expanded syndrome; gestosis

Since the late nineteenth century, it has been recognized that pregnant women may manifest disease of several organs, many times in association with hypertension. Together, the 1913 edition of DeLee's *The Principles and Practice of Obstetrics*[1] and the 1912 edition of *Williams' Obstetrics*[2] considered as examples of toxemia of pregnancy diseases such as headaches, hyperemesis, dermatitis (herpes gestationalis, impetigo herpetiformis), yellow atrophy of the liver, chorea gravidarum, psychosis, and hypertension. In 1937, the American Committee on Maternal Health presented a more confined classification of toxemia, which was limited to hypertensive disease, renal disease, preeclampsia (severe or mild), eclampsia, vomiting of pregnancy, acute yellow atrophy of the liver, and "unclassified" toxemia.[3] However, the fourteenth edition (1971) of *Williams' Obstetrics* spoke disparagingly of the term "toxemia" and further limited the disease to only hypertensive disorders.[4] While there has been continuous redefinition of the abnormality with each new edition of *Williams' Obstetrics*, the seventeenth (1985) edition mentions the term toxemia only to condemn it as "unsatisfactory."[5]

The editors of the latest edition of *Williams' Obstetrics* do not discuss how their suggested term for toxemia, pregnancy-induced hypertension, applies when a pregnant woman is desperately ill with pregnancy-related thrombocytopenia, subcapsular liver hematoma, and liver dysfunction but has little or no hypertension. While such cases of toxemia occur infrequently, they remain a significant cause of preventable maternal deaths,[6] in part, because such pregnancy-induced illnesses are often considered medical rather than obstetric in origin. Thus there appears to be a modern need for retaining the obstetric concept of toxemia.

Presented here are examples of polysymptomatic diseases (gestosis) involving more than two organ systems occurring in pregnant women, which are resolved by delivery. The term gestosis as used here refers to a pregnant woman who is ill and has symptoms arising from several target organs.

Material and methods

Fifty-nine normotensive ill pregnant women, seen either at the University Hospital in Denver or in Omaha, with possible gestosis (according to the definition of multiple target organs being affected), were studied for presence of elevated digoxin and human chorionic gonadotropin (hCG) levels, abnormal uterine souffle, venous reactivity, and relative hypovolemia. All women were apparently in good health without disease between pregnancies. There were no maternal or perinatal deaths.

Venous reactivity was obtained with the leg plethysmographic technique and plasma volume was determined with the Evans Blue method as previously described.[7] Venous reactivity was considered abnormal when the relative resistance ratio was >0.13 and plasma volume was abnormal when the value was below 48 ml/kg. hCG was considered abnormal when the urinary Gravidex test was positive after the urine had been diluted 1:20 with saline solution. The placental bed was located with ultrasound and the maternal flow was considered abnormal when Doppler examination showed reduced diastolic flow either on the cathode-ray tube screen (with a dicrotic notch) or with the audible monitor. The serum digoxin level was determined with the Abbott fluorescence polarization TDX system with serum values >0.2 ng/ml of digoxin equivalent being considered abnormal.

Results

Of the 59 initial subjects, in 12 patients either sustained hypertension developed or the medical problem

From the Department of Obstetrics and Gynecology, University of Colorado Health Sciences Center, and the University of Nebraska Medical Center.
Presented at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.

resolved before delivery. In addition, 10 demonstrated signs of normal plasma volume expansion (decline in hematocrit, normal amniotic fluid volume, and a loud pulmonic flow murmur). Thus 37 subjects were available for laboratory confirmation with our special tests for gestosis. Plasma volume determinations were performed in 29 patients (78%), urinary hCG levels were estimated in 31 (83%), serum digoxin levels were determined in 27 (71%), placental souffle diastolic flow was monitored in 32 (84%), and venous reactivity was examined in 37 (100%) cases. Table IA shows the percentages of the abnormal special tests that were apparently associated with pregnancy-induced illness. A pregnancy-induced illness was defined as one that persisted through delivery but was apparently resolved within a 2-week postpartum period.

There were 10 cases of pregnancy-related medical problems (albuminuria, blindness, dermatitis, pruritis, headaches, persistent heart burn, or upper abdominal pain) in which all patients had abnormal hCG levels, digoxin levels, venous tone, plasma volume, and uterine souffle. In Table IB are presented eight examples of gestosis with an initial blood pressure <140/90 torr and no evidence of diabetes mellitus at hospitalization. In addition to having multiple target organs affected, the fetuses were growth retarded. There were four other women who also apparently had pregnancy-induced illness, but one had no other abnormal tests and two had abnormal venous tone and were hypovolemic. One fetus was growth retarded.

Comment

As shown in Table II, a case of gestosis is a "sick" pregnancy with increased risk of perinatal and maternal morbidity and/or mortality. Hypertension may be severe but is often mild or absent. While gestosis is usually demonstrated in the third trimester of the first pregnancy, it may occur during any stage of any preg-

Table II. Expanded toxemia syndrome or gestosis

1. Variation in target organ expression described for more than 100 years[10]
2. Frequency of various target involvement apparently influenced by race. The two apparent extremes are in blacks, who often have only preeclampsia, and in Native Americans, who frequently have the polysymptomatic forms
3. Usually associated with failure of uterine spiral arteries to dilate and plasma volume expansion to occur (hypovolemia and hemoconcentration)
4. Often associated with elevated maternal hCG or "hyperplacentosis"
5. Fetal growth retardation or dysmaturity usually present. Oligohydramnios may occur for only short time periods during pregnancy
6. Gestosis can be threatening maternal and fetal disease, even in absence of hypertension
7. Maternal illness resolved by termination of pregnancy

Table III. Target organ or disease complexes of expanded toxemia syndrome

1. Autoimmune: negative or positive antinuclear antibodies; positive platelet antibodies (with thrombocytopenia); lupus-like syndrome
2. Central nervous system: seizures; headaches; cortical blindness
3. Dermatitis: herpes gestationalis (pemphigoid gestationis); Spangler's papular dermatitis; impetigo herpetiformis; prurigo gestationis (polymorphic eruption of pregnancy; toxemia rash of pregnancy
4. Eyes: retinopathy; retinal detachment
5. Hypertension: gestational hypertension; chronic hypertension
6. Hypovolemia: hemoconcentration; prerenal azotemia; hyperviscosity
7. Gallbladder: thickened wall; incidental cholelithiasis
8. Gastrointestinal: duodenal ulcer; gastrointestinal bleeding; upper abdominal pain responding to cimetidine
9. Liver disease: hyperemesis gravidarum; intrahepatic cholestasis; gestosis (toxemia); acute fatty liver; hemolytic anemia; megaloblastic anemia; subcapsular liver hematoma
10. Pancreatitis: elevated serum amylase, frequent in Native Americans
11. Preeclampsia: pregnancy-induced hypertension; edema-proteinuria-hypertension gestosis
12. Thrombocytopenia: idiopathic thrombocytopenia purpura; thrombotic thrombocytopenic purpura; hemolytic uremic syndrome; gestosis
13. Renal: nephrotic syndrome; preeclampsia; acute renal failure

nancy, even if the previous pregnancies were apparently normal. Preeclampsia or gestational hypertension, while often a very significant part of the gestosis complex, will not be discussed since the therapy is well known. Instead, the expanded toxemia syndrome will be presented from the concept of "gestosis," the "toxemic" dermatitis, autoimmune diseases, spiral artery and plasma volume changes, hyperplacentosis, venous reactivity, and technique of diagnosis.

Gestosis. Some of the clinical features of gestosis are presented in Tables II and III. In 1975, I presented to this society a series of cases of pregnant women with multiple organ involvement including liver abnormalities, gastrointestinal bleeding, blindness, etc. The patients were selected because they all had pregnancy-related thrombocytopenia and elevated serum transaminase values. I termed their disease process severe preeclampsia, although some of the pregnant women were not very hypertensive, had normal urinalysis results, and were in no apparent danger of having seizures. Nevertheless, they all were ill. In addition, many of these women were multigravid, some having had apparently normal first pregnancies. Since Chesley[8] has, at least for study purposes, strictly defined preeclampsia as limited to the first pregnancy and to pregnant women with abundant albuminuria, another term is needed to describe this expanded toxemia syndrome.

After World War II, the German-speaking obstetricians introduced the term gestosis. They used the letters EPH to refer to edema, proteinuria, and hypertension (EPH gestosis) and other letters to refer to symptoms such as thrombocytopenia (T) or liver disease (L).[9] In a second series of cases, we attempted to apply this terminology to describe the expanded toxemia syndrome as "EPH gestosis, type B," with type A being only those with severe preeclampsia.[10] This awkward term was replaced in the literature by Weinstein[11] with the acronym "HELLP syndrome." His term was well accepted, yet it often was applied to a pregnant patient with a subacute condition (in no immediate need of "hellp") who usually did not have clinical hemolysis, may not have had hypertension, and may have had involvement of organs other than those expressed in the term.[11] Since the term "toxemia" has been expunged from American textbooks and medical journals, it would appear that "gestosis" is the next best simple term to describe the expanded toxemia syndrome. Two conditions that are not usually considered examples of toxemia or gestosis, pregnancy-related dermatitis and autoimmune disorders, are also discussed.

Dermatitis. Papular dermatitis of pregnancy as described by Spangler et al.[13] is associated with elevated maternal hCG levels, depressed estriol levels, and a high fetal mortality rate. Other pregnancy-related dermatitides have been considered as toxemic rashes of pregnancy because of their associated maternal and fetal problems.[14] We described a series of cases of pruritus of pregnancy associated with elevated maternal hCG levels and maternal and fetal complications.[15]

Autoimmune disease. Autoimmune diseases during pregnancy are difficult to classify. Farnam et al.[16] concluded that the incidence of positive antinuclear anti-

Table IV. Laboratory tests to document presence of gestosis*

Test	*Target organ or system*
Antinuclear antibodies	Autoimmune disease
Amylase, serum	Pancreas
hCG[15]	Hyperplacentosis
Creatinine/blood urea nitrogen (serum)	Kidney, hypovolemia
Digoxin, serum	Natriuretic hormone
Glucose, blood	Hypoglycemia (liver)
Hematocrit	Hemoconcentration
Iron, serum	Erythropoiesis
Partial thromboplastin time, activated	Lupus anticoagulant Cardiolipin antibodies
Platelet antibodies	Thrombocytopenia
Platelet count	Thrombocytopenia
Pulmonary systolic murmur	Hypovolemia
Transaminases, serum (aminotransferase)	Liver
Ultrasound (level II)	Subcapsular liver hematoma Thickened gallbladder Oligohydramnios Dysmaturity
Uterine souffle with Doppler for diastolic flow	Presence of uterine arteriovenous fistulas

*Two or more tests should be positive in addition to chief complaint for diagnosis of gestosis.

bodies in pregnant women is significantly higher than in nonpregnant women. Depending on the laboratory techniques, from 5% to 100% of pregnant women with gestosis-associated thrombocytopenia have platelet antibodies. I have examined four patients with a systemic lupus erythematosus–like syndrome during pregnancy, which cleared with delivery, only to recur with subsequent pregnancies. Pregnant patients with apparent autoimmune disease often respond to steroids.[12]

Spiral artery changes and plasma volume expansion. In 1967, Brosens et al. demonstrated that structural alterations occur in the human uterine spiral arteries found in the decidual part of the placental bed. As a consequence of the action of cytotrophoblast on the spiral artery vessel wall, the normal musculoelastic tissue is replaced by a mixture of fibrinoid and fibrous tissue. The small spiral arteries become converted to large tortuous channels creating low-resistance channels or arteriovenous shunts. As early as 1903, Arguad, after studying the uterus in various pregnant mammals, noted these same spiral artery changes. He claimed these spiral artery alterations were encountered only in mammals adapted to live in the upright position during pregnancy. Brosens termed these normal spiral artery alterations "physiologic changes."

In dogs, when a surgically prepared arteriovenous shunt is opened, there soon appears a marked increase in the plasma volume, cardiac output, and retention of sodium of the animal. An apparent anemia occurs as the red blood cell mass is slower to expand. The reverse happens when the shunt is closed. The situation of opening arteriovenous shunts then is very much like early normal pregnancy, where there is an early increase in plasma volume and a resulting physiologic anemia as the red blood cell mass is slower to expand. Immediately after delivery, with closure of the placental shunt, associated diuresis and natriuresis occur. When the spiral arteries fail to undergo these "physiologic changes," as defined by Brosen et al., fetal growth retardation often occurs with preeclampsia. In 1983, Campbell et al. used gated, pulsed Doppler ultrasound to study the uterine arcuate arteries serving the spiral arteries and placenta in pregnant women. Among the patients who showed evidence of failure of the spiral arteries to dilate and increased vascular resistance, there was subsequently a high frequency of proteinuric hypertension, poor fetal growth, and fetal hypoxia.

Wells et al. demonstrated, in 1984, that the decidual spiral arteries that have been attacked by the cytotrophoblast have a fibrinod matrix that develops amniotic antigens, apparently to maintain the structural integrity of the vessel wall. Thus there are histologic and immunologic explanations for the presence or absence of the marked increase in uterine blood flow and plasma volume expansion seen in human pregnancies.

Hyperplacentosis. The concept of hyperplacentosis presented by Scott, in 1958, refers to an increased placental activity, usually increased maternal levels of hCG. Jeffcoate and Scott later demonstrated that many preeclamptic women have elevated hCG levels or hyperplacentosis, and subsequent studies have indicated that severe preeclampsia is associated with elevated maternal serum and urine hCG levels. Pregnancy-related dermatitis, especially pruritus associated with poor fetal outcome, is also associated with increased hCG levels.

Venous reactivity. In 1937, Nicholson J. Eastman suggested that instead of the concept of the renal system or the so-called "low reserve kidney," the dominant abnormality in toxemia of late pregnancy is the vascular system. The basis of his argument was "the constancy at which spasm of the retinal arterioles is met in these disorders." By contrast, our own studies have suggested that it is the venous rather than the arteriolar activity that is the significant abnormality in women with preeclampsia, as the veins contain at least 75% of the blood volume of pregnant women. However, whenever the sympathetic nervous system increases the vasomotor tone of the veins, it also constricts the corresponding arterioles. While venous vasodilatation may be incidentally achieved with therapy intended to produce arteriolar dilatation, our studies suggest that the apparent abnormal venous circulation should receive direct attention in the therapy of gestosis.[7]

Diagnosis. In order to appreciate the frequency of gestosis, it is necessary to perform several tests routinely in all pregnant women having significant medical abnormalities. Table IV lists some of the laboratory tests

reported to be abnormal in the expanded toxemia syndrome or gestoses. Unfortunately, the incidence of elevated serum transaminase levels in apparently normal pregnant women of the various racial groups, at term, is not known. Because of the increased platelet aggregation with gestosis, apparent thrombocytopenia determined on an electrical counter should be confirmed either by peripheral blood smear or by manual platelet count. To confirm normal plasma volume expansion, we auscultate with a stethoscope for the presence of a loud maternal pulmonic systolic flow murmur, and for uterine spiral artery dilatation we use a continuous Doppler device for the presence of loud diastolic flow in the maternal placental bed (iMEX 301).

Although we have a 9-year experience with the Swan-Ganz catheter technique, I no longer use it in gestosis cases.[10] While cardiac outputs and pulmonary capillary wedge pressures may be increased, unchanged, or decreased, these determinations have not been of clinical benefit and the procedure has been associated with significant maternal morbidity. By contrast, estimation of maternal venous tone is without apparent risk and in my experience provides clinically useful information.[7]

Therapy. With the exception of acute treatment for preeclampsia, obstetricians disagree on the concepts of treatment of gestosis. My concept is that the failure to dilate spiral arteries and to adequately expand plasma volume in the pregnant woman evokes increased venous reactivity and multiple maternal organ dysfunction. While the absence of the "physiologic changes" of the spiral arteries probably cannot be corrected, appropriate therapy can modify the abnormal venous reactivity and its associated maternal hypovolemia, if the diagnosis is made before the development of serious illness. Drugs that decrease venous resistance and lower venous tone include amyl nitrite, furosemide, nitroglycerin, prazosin, and tranquilizers such as hydroxyzine. If standard therapeutic measures do not correct the hypertensive and hypovolemic states by reducing blood pressure and venous reactivity, then treatment with prazosin and simultaneous expansion of plasma volume with 5% or 25% albumin seems appropriate. Steroids (topical triamcinolone acetonide, prednisolone tablets, or intramuscular dexamethasone) have been reported to improve the abnormal findings of patients with gestosis (dermatitis, liver dysfunction, platelet antibodies, lupus-like symptoms, and/or thrombocytopenia). Cimetidine often improves symptoms in those with upper abdominal pain and/or elevated amylase levels. Heparin is not indicated, but platelet transfusions are often successful in the short-term treatment of thrombocytopenia.

The use of diuretics in preeclampsia has been condemned by obstetricians on the basis of the concept that they reduce blood volume or placental perfusion.[5] However, as noted in a review of randomized trials of diuretics in preeclamptic pregnancy by Collins et al., diuretics apparently reduced the incidence of stillbirths by one third. Many diuretic agents decrease venous tone and increase venous capacitance and their hypovolemic effect is temporary. While such agents are often used to prevent pulmonary edema during the course of active plasma volume expansion with colloid agents in preeclamptic patients, part of their efficacy may be due to their effects as venous vasodilators.

In conclusion, it serves no useful purpose to categorize all medical diseases associated with pregnancy as "gestosis"; rather only those associated with detrimental maternal and/or fetal effects should be so classified. This article has emphasized the expanded nature of the syndrome, but accepted concepts and therapy[5] for preeclampsia-eclampsia must not be ignored.

The additional clinical implications of the concepts of "gestosis" beyond those of simple preeclampsia or pregnancy-induced hypertension are: (1) there are several mild to severe polysymptomatic diseases with or without multiple target organ involvement associated with pregnancy, which regress with delivery; (2) the common feature in gestosis of relative maternal hypovolemia indicates that many of these pregnancies are at risk for serious maternal and fetal complications, even in the absence of maternal hypertension; (3) while each one of the symptom complexes or target organs may have a suggested form of therapy, the presumed failure of the "physiologic change" of the spiral arteries or other uteroplacental abnormality probably limits any therapy other than delivery; (4) nevertheless, in addition to standard preeclampsia therapy, steroids and/or techniques to achieve plasma volume expansion appear to aid many of the patients with gestoses; (5) while platelet transfusions may be necessary, heparin should not be used; (6) the gestoses are usually most severe in (or even limited to) the third trimester of the first pregnancy, but the multigravid woman may be a victim of the severe multiple organ involvement even after a normal prior pregnancy; (7) after a pregnancy with gestosis, there is usually a reduced risk with subsequent pregnancies, but it may also be more severe or in a different form in subsequent pregnancies. For those patients having had pregnancy-related thrombocytopenia, prophylactic low-dose aspirin therapy may be indicated early in subsequent pregnancies. Maternal tranquility and adequate diet may also ameliorate the disease process.

Discussion

DR. EDWARD J. QUILLIGAN, Sacramento, California. This article by Dr. Goodlin examines the concept that pregnancy can induce or be associated with abnormality in an organ or organs other than the vasculature or kidneys in a manner similar to pregnancy-induced hypertension. He calls this the expanded toxemia syndrome or gestosis. He examined 59 pregnant women who were in apparent good health between pregnancies and who developed multiple organ disease without hypertension during pregnancy. The examination included venous reactivity, blood volume, and hCG. Ten pregnant women had an elevated venous reactivity and hCG level if I read the article correctly. He gave eight examples of patients with gestosis including toxemia, skin rash, positive antinuclear antibody test, cortical blindness, thrombocytopenia, nephrotic syndrome, liver dysfunction, pancreatitis, and cholecystitis. I do not know what happened to the other two and my first question to Dr. Goodlin would be why he did not include them.

He went on to develop the hypothesis that gestosis is due fundamentally to a failure of adequate plasma volume expansion caused, at least in part, by a failure of adequate dilatation of the spiral arteries, the same concept that some feel is responsible for pregnancy-induced hypertension. He then discussed the diagnosis and therapy of gestosis in view of his concept of the pathogenesis. The diagnosis should feature reduced plasma volume, and therapy is directed toward increasing plasma volume. This is somewhat oversimplified since there are other tests involved in the diagnosis of thrombocytopenia, for example, and other therapies. These tests and therapies will vary depending on the organ system or systems involved.

Dr. Goodlin's concepts may be correct. He certainly has developed many novel, interesting, and important concepts during the past several years; however, I think this one needs more proof before therapy is based on it. Equating venous reactivity with decreased plasma volume may be a quantum leap that needs proving. My next question would be why he did not compare plasma volumes in the 10 patients with abnormal venous reactivity with those of 10 of the patients with a disease similar to gestosis but normal reactivity and those of 10 normal control pregnancies at matched gestational ages. If this could not be done, was there any other evidence of failed volume expansion in the gestosis patients, such as an elevated hematocrit?

The failure of the spiral arteries to expand is due to the lack of trophoblastic invasion, which proceeds throughout the first and second trimesters. Examination of the basalis may show this change or lack of the same. Were any biopsies done with this in mind?

The work of Campbell quoted in this article is exciting in that it shows a reduction in ultrasonically determined uterine blood flow, which precedes the onset of pregnancy-induced hypertension However, these studies are not universally accepted as indicative of uterine blood flow and, assuming they are correct, similar studies need to be performed in the gestosis patients before one can assume reduced blood flow in these patients.

Finally I would like to say a word about therapy. Dr. Goodlin has suggested, and I quote, "If standard therapeutic measures do not correct the hypertensive and hypovolemic states by reducing blood pressure and venous reactivity, then treatment with prazosin and simultaneous expansion of plasma volume with 5% or 25% albumin seems appropriate." In my opinion use of plasma volume expansion with or without vessel dilators requires some very carefully controlled studies before it can be recommended. There have been too many instances of congestive heart failure with plasma volume expansion used in patients with pregnancy-induced hypertension.

As always, I enjoyed Dr. Goodlin's article because, whether he is right or wrong, he always has interesting and provocative ideas.

DR. MERLE ROBBOY, Newport Beach, California. I would like to ask Dr. Goodlin if he feels that the hyperemesis gravidarum syndrome is part of his gestosis picture. What would he do with a patient who has this disease that extends into the second trimester?

DR. JULIAN PARER, San Francisco, California. Dr. Goodlin, what you appear to have done is take a group of patients with abnormalities and discard hypertension as one of the diagnostic features. It seems to me that if you do a whole host of laboratory tests on a group of totally normal women, you are bound to come up with abnormalities in some of them. My question is how do these people present? What are their symptoms and how do you pick up this disease?

Dr. Richard Paul, Los Angeles, California. In the management of these patients, I wonder what role activity or nonactivity plays. Of what benefit is the therapy of bed rest? Does that improve the condition and, if so, by what mechanism?

Dr. Kelvin Churches, Carlton, Australia. I would be interested if Dr. Goodlin would explain why he so summarily dismissed the use of heparin, as this is fairly routine treatment for severe preeclampsia at the Royal Victoria Women's Hospital in Melbourne.

Dr. Goodlin (Closing). I will answer Dr. Churches' question first. The use of heparin in these cases can be a disaster. In my experience in the last 20 years I have seen these women being admitted having had 80 to 90 units of blood and plasma after thrombocytopenia was treated with heparin. They have associated subcapsular liver hematomas. Maternal deaths are associated with the use of heparin.

I think that heparin should never be used under these circumstances. As I tried to indicate, if thrombocytopenia is a significant problem, platelet transfusion works. I have had anesthesiologists and hematologists tell me that "platelet transfusion won't work because the associated antibodies will destroy the platelet," and, in my experience, that is not true. Bed rest, Dr. Paul, I agree is the *sine qua non* of all these therapies. I think the most successful way that one can achieve plasma volume expansion in hypovolemic pregnant women is with bed rest and tranquility.

Dr. Parer asked what symptoms these pregnant women had. I studied hospitalized women who had any symptoms of the various target organs that I mentioned who were pregnant. I do not know the percentage of otherwise normal pregnant women who have thrombocytopenia, but I assume that if they do have thrombocytopenia then that is significant. And the same with elevated liver enzymes. The digoxin levels have proved very useful for diagnosis. So I was simply looking at ill pregnant women who were hospitalized, who had all types of alleged medical diseases, and seeing if I could fit them into the definitions of gestosis. And, as I said, of the 59 that I studied, at least 10 of them had the "disease." To answer Dr. Quilligan, two of the women had a nephrotic syndrome and two had the lupus-like syndrome.

The issue of plasma volume expansion is for me an almost emotional one. I have become less enthused for the technique because nowadays we have to get women only to the twenty-eighth week of pregnancy in order for the neonatalogist to have an excellent outcome of the newborn infant. When I started this oncotic therapy in the 1960s we had to prolong pregnancy to 34 weeks. So plasma volume expansion, I will concede, really does not have the role I thought it had 15 or 20 years ago. I still think it is very useful for the signs of fetal distress in hypovolemic women or if you wish to use an epidural anesthetic. I think the group from Australia has shown in a very elegant way that plasma volume expansion works in women with toxemia or gestosis. However, it may not be necessary; it may be simpler just to deliver these women and let the neonatologist struggle with the neonate. Minipress (prazosin) is the only antihypertensive drug that appears to dilate veins. It is an α-adrenergic receptor blocker, and that is why I think it makes sense to use in expanding plasma volume in hypertensive pregnant women.

I think, at least from published results, I have seen more cases of pulmonary edema than anyone. In my experience it is easily handled with furosemide. Many physicians do not make the diagnosis of pulmonary edema because they do not obtain a chest x-ray film when dyspnea or chest pain occurs. The simplest way to avoid pulmonary edema, when using oncotic therapy, is to note whether the women undergo diuresis after the plasma volume expansion, or if there is a lowering of the hematocrit. If not, it is the wrong therapy. Another feature is to make certain that these women are sitting upright.

I think the uterine Doppler studies are well established, and I have used them since 1974. I attended the World Congress on Hypertension in Amsterdam last year and the United States was about the only country that did not have a paper on the use of Doppler and the arcuate artery or placental bed studies. The Soviet Union, Israel, Germany, Japan, France, England—all over the world people have picked up on this, and, to me, it is another example how America lags behind the rest of the world. The Doppler studies indicate by 22 weeks which pregnancies are at risk.

The group in London obtained a 2 cm cube of the placental bed in order to study the spiral arteries. They apparently invert the uterus at the time of cesarean section and obtain this tissue. I have never been able to obtain permission from our experimental study group for this project. We have tried repeatedly to study the spiral arteries with simple scraping or looking at the placental surface and have failed. I agree that the hematocrit is useful.

Liley, the great New Zealand investigator, showed, in 1970, that if a pregnant woman has a high hematocrit the odds are 4 to 5 that she is hypovolemic, and if she has a low hematocrit, she is not anemic four out of five times, but it is probable that the plasma volume has expanded.

As far as the study group is concerned, all of these women had plasma volume studies. As I recall, 40% were considered to be hypovolemic but did not have the required elevated hCG and digoxin levels or had normal Doppler studies. R values were high.

Severe hyperemesis can be gestosis and can be treated as toxemic. I have used steroids when the liver enzymes were elevated and oncotic therapy when there was hypovolemia after ruling out hyperthyroidism.

Analysis of the significance of discolored amniotic fluid detected at midtrimester amniocentesis

Elinor M. Zorn, M.D., Frederick W. Hanson, M.D., L. Carl Greve, Ph.D., Barbara Phelps-Sandall, M.S., and Frances R. Tennant, Ph.D.
Davis, California

In 110 midtrimester amniocenteses of the 3349 procedures done at the University of California, Davis, Medical Center between 1979 and 1984, the fluid obtained was noted to be discolored. The significance of this finding was evaluated with review of pregnancy history and outcome and by using biochemical techniques. A significant increase in miscarriage was seen in the pregnancies where discolored fluid was obtained (9%), in comparison with the entire group of pregnancies in which amniocentesis was done at the same institution over the same period (1.6%). This increase was most marked in the pregnancies in which, in addition to discolored fluid, there was a prior history of pregnancy bleeding. Thirty-four discolored fluid samples and 18 clear fluid samples were studied with spectrophotometry, electrophoresis, isoelectric focusing, and chromatography. These studies indicate that in most cases the discoloring pigment is blood rather than fetal bowel contents, as had been suggested by others. (AM J OBSTET GYNECOL 1986;154: 1234-40.)

Key words: Amniocentesis, midtrimester, amniotic fluid, discolored, abortion

Green or brown discoloration of fluid obtained at midtrimester amniocentesis has been a concern of many investigators. The incidence has been reported to vary between 1% and 7% of procedures performed. Association with a history of bleeding during early pregnancy and with prior unsuccessful amniocentesis has been noted. The significance of the finding has been a subject of much debate, with some authors noting fetal demise in as many as 30% of pregnancies with discolored fluid[1, 2] and others finding little or no increase in adverse pregnancy outcome.[3-7]

Surprisingly little investigation has been done into the cause of the discoloration. Various authors have assumed it to be blood,[6] either of fetal or maternal origin, or meconium.[1, 3-5, 7] Most authors base their statements about the cause of the discoloring substance on spectrophotometric studies,[3, 4] although it is clear that both blood and meconium give an absorbance peak in the 405 nm range.[8] Hankins et al.[6] have added a guaiac test (Hemoccult, Smith Kline & French Laboratories, Philadelphia) of the fluid. Allen[7] distinguishes between blood-stained fluid (brown) and meconium-stained fluid (green) on the basis of visual appearance, having excluded the brown fluid samples from his study.

In this study an attempt was made to look at both the outcome of the pregnancy and the cause of the discoloration of the fluid.

Material and methods

For this study all amniocenteses in which the amniotic fluid was noted to be discolored by visual inspection by the obstetrician performing the procedure were selected from a series of 3349 amniocenteses performed for standard genetic indications. A total of 110 discolored fluid samples (3.3%) were evaluated. Charts were reviewed for pregnancy information routinely obtained prior to the procedure. Questions asked as part of the preamniocentesis counseling session included screening questions for pregnancy complications such as uterine cramping, bleeding, or illness, as well as questions on exposures to medications or x rays. The delivering physician was contacted for pregnancy outcome information, including date of delivery, length of gestation, birth weight, and any noted abnormalities of the infant. The incidence of adverse outcome was then compared with the outcomes seen in the entire amniocentesis group. In assigning pregnancies to abnormal outcome groups, each pregnancy was placed into only one such group. Thus, if a pregnancy ended with a premature live-born infant who subsequently died during the neonatal period, the pregnancy was assigned to the prematurity group and not to the neonatal death group. The decision to make this assignment was based on the fact that most of the information regarding outcome came from the obstetrician's office. Often those records did not include information about the ultimate

LMP = Last menstrual period.

*The amniocenteses were performed at the University of California, Davis Medical Center.

†In most elective terminations, a major fetal abnormality was documented prior to the decision to terminate.

‡These unanticipated abnormalities noted at delivery included cleft lip, congenital heart disease, syndactyly, etc. None would have been expected to be diagnosed by amniocentesis.

resolution of the neonatal course. Within the group of discolored fluid samples, outcomes of pregnancies in which there was a history of bleeding during pregnancy were compared with those in which there was no history of pregnancy bleeding.

Amniotic fluid samples from 52 procedures were examined by four independent analytic techniques: (1) sodium dodecyl sulfate (SDS) electrophoresis, (2) isoelectric focusing, (3) gel filtration chromatography, and (4) visible wavelength spectrophotometry. Of the fluid samples examined, 18 were chosen because they were judged to be clear by the clinician responsible for the amniotic taps and were considered to be representative of normal amniotic fluid. All of the remaining 34 fluid samples that were examined were from the group considered to be discolored, although the range of discoloration varied from slight to extreme. Gut contents from two fetuses electively aborted with prostaglandin (dinoprostone [Prostin E2], Upjohn Company, Kalamazoo, Michigan) at 15 and 18 weeks' gestation were subjected to the same analytic techniques as the amniotic fluid samples. The SDS electrophoresis followed the procedure of Fairbanks et al.[9] and employed resolving gels of 18% acrylamide. Gels of this unusually high acrylamide content were necessary to cleanly resolve the heme pigments and the pigments found in fetal gut contents. Isoelectric focusing was performed according to the methods of Vesterberg et al.[10] Gels of 7% acrylamide were used in most experiments. Gel permeation analysis of the amniotic fluids was carried out with the use of a G-100 Sephadex column (50 by 1.4 cm) with an elution buffer of 100 mmol sodium orthophosphate (pH 7.8).[11] Analysis of each chromatographic run was performed with a Gilson Holochrome column monitor measuring the A^{200} absorbance of the column effluent.[10] Spectrophotometric analysis was done with a Beckman DB photospectrometer by methods similar to those of Liley.[7]

Analysis of results. Table I compares the outcome of pregnancies in which discolored fluid was obtained to the outcome of the 3349 procedures done at the same institution during the same period. Most samples were obtained from procedures performed by one of us (F. W. H.). The overall outcome of most of these procedures was the subject of a previous report.[12] Ten women (9%) with discolored fluid went on to miscarry prior to 28 weeks' gestation, in comparison with 1.6% in the overall group. One pregnancy ended in stillbirth (1%). This did not differ from the overall stillbirth rate of 1%. Three fetuses had abnormal chromosome patterns. One fetus had trisomy 21 and was electively aborted. Two other fetuses had inherited balanced translocations. One female fetus had inherited a translocation (Y;22) from her father. She was examined at 1 year of age, and no abnormalities were noted. The other case involved a translocation (7;16) inherited from the mother. The pregnancy was complicated by fluid leakage and oligohydramnios prior to the amniocentesis. Delivery occurred prematurely, and the baby was transferred to another neonatal intensive care unit. After a difficult neonatal course, the baby was discharged home. Six women were delivered prior to 35

weeks' gestation, and two pregnancies produced babies that were small for dates. Of 44 sets of multiple gestation in which amniocentesis was done, discolored fluid was found in one. Discolored fluid was present in only one sac. These twins were dizygotic, and the twin in whose sac the discolored fluid was found was anencephalic. The pregnancy was continued to term, and both twins were live born. The anencephalic twin died at 5 days of age. The outcome group labeled "undetectable abnormalities" includes such birth defects as cleft lip and palate, congenital heart disease, and syndactyly. None of these abnormalities would have been expected to have been identified at amniocentesis or with the accompanying ultrasound test. In one procedure yielding clear amniotic fluid, the fetus was born at term with an abdominal perforation thought to be related to the amniocentesis. This was the only fetal injury seen in 3349 amniocenteses.

Of 110 pregnant women with discolored fluid samples, 69 (62%) gave a history of bleeding prior to amniocentesis (Table II). There were nine instances in which the discolored fluid was found on a repeat tap. In one case a repeat amniocentesis was done because of failure of cell culture from the first tap. The initial fluid was clear, but at the subsequent tap 3 weeks later, discolored fluid was obtained. In the remaining eight cases, in which repeat amniocentesis was done at a subsequent visit, no fluid had been obtained at the initial procedure. In all but two of these, both taps were done at the University of California, Davis, Medical Center. Two patients were referred when the initial attempt in the referring physician's office was unsuccessful. In three of these repeat taps, there was a history of bleeding in the pregnancy prior to the amniocentesis, and in all cases the pregnancy ended with the birth at term of a normal child. In nine of the ten miscarriages that occurred in the group with discolored amniotic fluid, a prior bleeding history was noted (13% of all pregnancies in which discolored fluid and a history of bleeding prior to amniocentesis were noted), in comparison with one (2%) in the group with discolored fluid but no history of bleeding. In addition, the twins, the small-for-dates babies, and three of the four premature infants were in the group with a preamniocentesis history of bleeding.

All discolored fluid samples demonstrated a spectrophotometric peak at 405 nm. High peaks were noted when the fluids were more visibly discolored. Although no peak was defined in the clear fluid samples, there was some absorbance at 405 nm in these fluids also. Aside from the height of the peak, no difference was noted among the variously discolored fluid samples on photospectrometry. On SDS electrophoresis, isoelectric focusing, and gel chromatography, it was possible to detect three different patterns. Of the 34 fluid samples, 31 contained a pigment that migrated with the blood of an adult man and was presumed to represent hemoglobin and its breakdown products. One fluid sample contained no blood pigments but contained a pigment that migrated with a pigment found in fetal gut contents. Two fluid samples contained both the heme pigment and the meconium pigment. Figs. 1 and 2 are examples of SDS electrophoresis and gel permeation chromatography, respectively. In an examination of lanes 6 and 7 of Fig. 1, *A*, it will be noted that the protein bands corresponding to serum albumin and other unidentified amniotic fluid proteins are absent. The bands are of course expected, and their absence is disconcerting. The difficulty, however, can be resolved by inspection of Fig. 1, *B*. In this illustration you see decreasing concentrations of green fluid, which shows increasing clarity of the expected protein bands. Apparently the materials from the green fluid are deleterious to the resolving efficiency of the Fairbanks system. At concentrations high enough to clearly show the green pigment, they completely interfere with the resolution of albumin, etc. Decreasing the concentration of the fetal gut contents did not change its staining pattern appreciably. Fig. 2 depicts G-100 chromotography of green fluid *(A)*, brown fluid *(B)*, and clear fluid *(C)*. The point of interest is the large peak at fraction 39 in Fig. 1, *A*, which is absent in *B* and *C*. This peak represents the low-molecular-weight green pigment seen in Fig. 1, *A* and *B*.

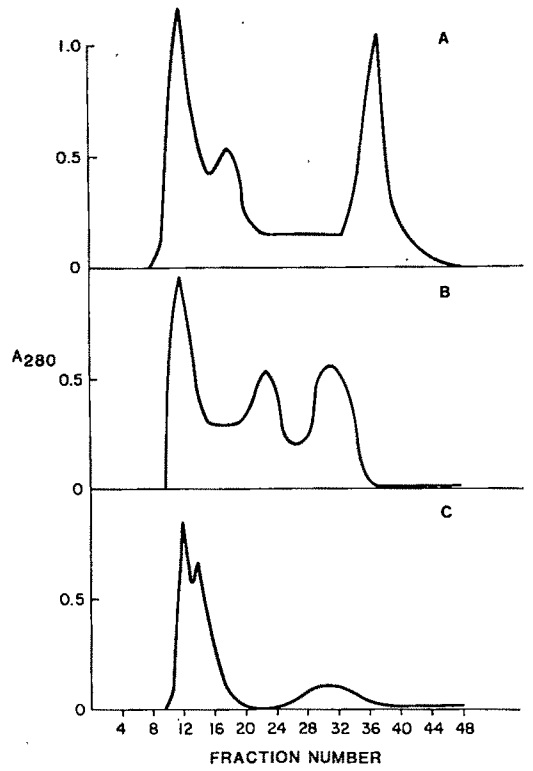

Fig. 2. Gel permeation chromatography of amniotic fluids. One-milliliter samples of green *(A)*, brown *(B)*, and clear *(C)* amniotic fluid was chromatographed on a 50 × 14 cm G-100 Sephadex column, with 100 mmol sodium orthophosphate (pH 7.8) used as the elution buffer. Fraction volume equaled 1.7 ml.

Comment

In this study of 110 discolored amniotic fluid samples, there was a 9% incidence of miscarriage, a significant increase over the 1.6% miscarriage rate of the total amniocentesis group ($p = 0.005$). We therefore conclude that these pregnancies are at increased risk for adverse outcome and that it is appropriate for the obstetrician who is managing such a pregnancy to note the finding. In particular, those pregnancies with both discolored fluid and a history of early bleeding are at highest risk, with a 13% miscarriage rate. Other adverse

outcomes, such as stillbirth, chromosome abnormality, or other birth defects, did not appear to be increased in this group.

Although it is certain that the large majority (33 of 34) of discolored fluid samples examined by our group contained hemoglobin as the major discoloring agent, it is clear that there are a small percentage (3 of 34) that contain a different pigment, either by itself or with the hemoglobin. This second pigment has physical characteristics similar to those of material derived from the gut contents of the two aborted fetuses, suggesting fetal "meconium" as the source of the pigment.

On the basis of the analytic studies, discolored amniotic fluid samples can be divided into at least two different groups. Some fluid samples contain blood contamination, whereas in others the discoloration appears to be due to fetal defecation into the amniotic fluid. It does not appear possible to distinguish fluids stained with blood from those stained by intestinal contents either by visual or by spectrophotometric means. It appears that other analytic techniques (SDS electrophoresis, gel chromatography) are necessary to detect the presence of "meconium" in stained amniotic fluid. Although there is little information available about when fetal defecation begins, the work of Abramovich and Gray[13] suggests that the fetus defecates "routinely" until 18 to 20 weeks' gestation, when defecation appears to stop. They suggest that defecation may stop because of innervation of the anal sphincter. If this is the case, one might question the ability of the fetus to defecate in response to stress prior to that time. One could assume that meconium in the amniotic fluid prior to 20 weeks' gestation is just a chance occurrence without prognostic significance. The finding of blood, on the other hand, might portend a poorer prognosis. Further studies are needed to determine the significance of amniotic fluid discolored by meconium in comparison with fluid discolored by blood. In addition, it would be useful to look at the outcome when maternal, in comparison with fetal, blood has stained the fluid. Techniques used in this study did not permit such a distinction to be made.

The mechanism that relates discolored fluid to adverse outcome can only be a subject of hypothesis at this point. If the blood causing discoloration is fetal in origin, subsequent adverse outcomes may be due to the volume of blood lost. If it is maternal, its presence may reflect interference with the fetomaternal circulation by a compromised placenta, which might be due to resolution of bleeding caused by fibrosis or to a partial separation of the placenta after bleeding has occurred into it. It is also possible that such early bleeding might in some way compromise the ability of the fetus to tolerate the stress of labor.

Discussion

Dr. Richard Allen, Portland, Oregon. Dr. Hanson and colleagues are once again to be congratulated for the excellent research on this interesting and, until recently, seldom-reported phenomenon. Earlier papers on this subject were hampered by small numbers in their series, but with the report in this presentation and that in two other articles in the last year, one by Hankins and colleagues in Dallas and my own article, we now have three large series with fairly comparable results. Most authors found discolored fluid in 1% to 2% of their amniocenteses. Hankins had an incidence of 6.8% with both green and brown fluid. Dr. Hanson's series last year had an incidence of 3.1%, which included transplacental taps 28% of the time—a procedure that one would expect to increase the number of bloody taps. In this article the incidence is 3.3%.

Hankins and colleagues assumed that almost all the discolored fluid samples were discolored by blood, even though most fluid samples were visually green. In conversations that I had with Dr. Hanson last year, we both believed that we could visually distinguish meconium from blood. However, it may well be that we are seeing green fluid in which the discoloration is indeed caused by blood breakdown products. The report by Dr. Hanson and colleagues does have the advantage that "most" of the amniocenteses were done by a single physician (himself).

Dr. Hanson cites a miscarriage rate of 8.2% (9/110), which is slightly higher than the fetal loss rate of 5.06% in my findings. However, the use of 28 weeks as the cutoff definition between miscarriages and premature delivery is somewhat arbitrary. Most tertiary care centers consider delivery at 26 to 28 weeks to result in potentially viable fetuses and not miscarriages. Dr. Hanson's nine cases also include three with abnormal chromosomes; one of these pregnancies was terminated, and one produced an anencephalic twin. I doubt that any of these amniocenteses would have shown discolored fluid for those reasons, per se. Even with the stillborn fetuses, most did *not* have discolored fluid. Therefore it is difficult to conclude that the outcome of these cases had anything to do with the color of the amniotic fluid. In addition, the results of α-fetoprotein testing is not mentioned, but I assume that the level was checked in all cases. Surely the anencephalic twin had an elevated α-fetoprotein level.

In Dr. Hanson's presentation, 62% of those patients with discolored fluid had a history of intrauterine bleeding prior to amniocentesis. I expect that fact to have a significant impact on the findings of discolored fluid. The fact that nine of these patients (13%) had bloody fluid on a repeat tap might also artificially skew the figures, since all of these pregnancies had a normal outcome. I am also puzzled by the fact that in eight of these cases, no fluid at all was obtained on the first tap. I'm sure these taps were all done under the guidance of ultrasonography. Were they done at a very early gestational age?

Since almost all the miscarriages occurred in patients with first-trimester bleeding, Dr. Hanson and colleagues conclude that the patients are at increased risk and need careful monitoring. Although I think we can all agree that any patient with early intrauterine bleeding is at some risk and needs to be monitored more closely, I'm not certain that this bleeding is necessarily related to the color of the fluid. Other factors, such as increased α-fetoprotein levels, may be much more significant. As concluded by myself and others, and as reported by Hankins and colleagues in 1984, "In the absence of an elevated alpha-fetoprotein, the pregnancy outlook is good despite the fact that an intraamniotic hemorrhage has occurred."*

As far as the cause of the discolored fluid is concerned, patients who do have first-trimester bleeding would account for most cases. I would think that this discoloration is almost always maternal, rather than fetal, in origin. In fact, in one of my cases of fetal death the patient later proved to have a large uterine septum on which the placenta was implanted. In addition, some of the cases are iatrogenic (caused by bloody taps and repeat taps), although as Dr. Hanson has previously shown, even transplacental taps should not portend an adverse outcome. In addition, as I pointed out in my article last year and as Dr. Hanson again cites, research by Abramovich and Gray have shown that meconium may be present as a normal physiologic defecation by the fetus in utero.

Last, Dr. Hanson wonders whether early bleeding compromises the ability of the fetus to tolerate the stress of labor, and yet we have no reported losses of term fetuses during labor.

Thus, if there is any relationship between discolored fluid and adverse outcome, in the absence of any other negative factors, it still remains hypothetical at this point in time. Rather, I still believe that we have further evidence, from Dr. Hanson's presentation, that most discolored fluid samples, regardless of whether the discoloration is caused by blood or meconium, do not portend an adverse outcome.

Dr. Robert C. Goodlin, Denver, Colorado. Until a few years ago, I did many amniocenteses, but then I thought that there's more to life [than amniocentesis].

*From Hankins GDV, Rowe J, Quirk JG, Trubey R, Strickland DM. Significance of brown and/or green amniotic fluid at the time of second-trimester genetic amniocentesis. Obstet Gynecol 1984;64:353-8.

However, I never, ever had the low complication rates that Dr. Hanson and colleagues have reported. I'm surprised, however, by their report because I can remember two cases in which the fetus had some abnormality in porphyrin metabolism, and this fluid looked dark and glowed. I can also remember three other cases in which we obtained stained fluid in which level 2 ultrasonography showed large, abdominal fetal wall defects. I believe that sometimes there's much more to stained amniotic fluid than blood and meconium.

Dr. Walter S. Keifer, Seattle, Washington. I'd like to ask Dr. Hanson to define the "Department of Pomology" for the secretary. There may be others here who might be curious also.

Dr. Hanson (Closing). We arbitrarily selected 28 weeks in looking at the miscarriage rate because it's so difficult, as I said last year, to go back into the literature and compare articles on amniocentesis for complications. Everybody has used a different definition, and thus we were being generous. We routinely check α-fetoprotein levels in all our amniotic fluid specimens, and the only patient who had an elevated level was the anencephalic infant, who also had discolored fluid. The one thing I regret is that one of our wells didn't contain α-fetoprotein. We could have then made a statement that there was no fetal blood in any of the discolored fluid.

With regard to not obtaining fluid in some taps, my geographic referral area is very large, extending all the way to the Oregon border and over to Nevada. Many patients at this time of year travel through some hazardous weather conditions and for long distances. I almost always feel obligated to attempt amniocentesis if there is any reasonable chance of obtaining fluid. We're not always successful, and some of these pregnancies are, indeed, at a very early stage. We're performing amniocentesis as early as 12 weeks now; I've even attempted amniocentesis in some 11-week pregnancies. We're getting excellent cell growth and obtaining fluid samples in most of these early amniocenteses. I wish to show that we can approach chorionic villus sampling with regard to the time at which amniocentesis can be performed.

In summary, the one point I definitely want to make here is that you cannot visually distinguish the origin of discoloration of the fluid; when brown is mixed with yellow, green appears in various shades. Spectrophotometric analysis doesn't help distinguish, either. In addition, our studies indicate that it's extremely rare to find meconium in the fluid. Although discolored fluid is a nonspecific finding, I believe it is associated with increased nonspecific morbidity and mortality. I believe that it does behoove the obstetrician to closely follow up on these patients, even though the vast majority will have an excellent pregnancy outcome.

Treatment of severe androgen excess due to ovarian hyperthecosis with a long-acting gonadotropin-releasing hormone agonist

Kenneth A. Steingold, M.D., Howard L. Judd, M.D., Roberta K. Nieberg, M.D., John K. H. Lu, Ph.D., and R. Jeffrey Chang, M.D.

Los Angeles, California

A 31-year-old nulligravid patient presented with irregular menses, severe hirsutism, and infertility. Evaluation revealed marked increases of serum androstenedione and testosterone levels and a possible ovarian mass. At operation a cystic teratoma was removed from the left ovary and bilateral wedge resection revealed severe ovarian hyperthecosis. After operation only a transient decrease of androstenedione and testosterone was noted and the patient failed to ovulate or improve clinically. Subsequently a long-acting gonadotropin-releasing hormone agonist was administered daily for 6 months, which reduced circulating Δ^4-steroids and estrogens to levels approximating those of castrated women. Immediately after discontinuation of treatment, ovulation induction was successfully achieved with human menopausal gonadotropin. This report introduces a new therapeutic approach to the problem of severe ovarian hyperthecosis and may provide an opportunity for childbearing in these patients. (Am J Obstet Gynecol 1986;154:1241-8.)

Key words: Hyperthecosis, GnRH agonist, androgen excess, testosterone

The term hyperthecosis was introduced in 1943 to describe isolated nests of luteinized cells distributed throughout the ovarian stroma.[1] In 1949, Culiner and Shippel[2] proposed the syndrome of hyperthecosis, which associated typical pathologic findings with the clinical symptomatology of hyperandrogenism and anovulation. Since recognition of this syndrome, acceptable therapeutic approaches have been difficult to identify and generally have been unsuccessful.

Eradication of androgen excess has been achieved by bilateral oophorectomy but only at the expense of future fertility.[3] In patients desirous of pregnancy, ovulation induction with clomiphene citrate has not been successful and ovarian wedge resection has been attempted. Responses to this procedure appear to reflect the severity of disease. Patients with mild hyperthecosis, characterized by slight elevations of serum testosterone, usually experience transitory reductions in testosterone levels and only temporary resumption of ovulatory function.[4] In more severe cases, manifested by higher elevations of serum testosterone and virilizing signs, ovarian wedge resection also elicits a temporary reduction in testosterone concentrations but fails to induce ovulation.[5] These patients are then faced with progression of masculinization and permanent infertility.

The present report describes a woman with severe androgen excess due to pathologically established ovarian hyperthecosis, in whom surgical management was unsuccessful. Subsequent treatment with a long-acting agonist of gonadotropin-releasing hormone resulted in complete suppression of ovarian androgen production, and immediately after cessation of therapy successful ovulation induction was achieved.

Case report

The patient, a 31-year-old Puerto Rican woman, gravida 0, was referred because of irregular menses and hirsutism. She experienced a normal puberty at age 12 years with regular menses associated with premenstrual symptoms. At that time she had no problem with weight gain or evidence of excessive hair growth. She did not use hormonal medications until age 25. At this point, she married, began to gain weight, and noticed that the menstrual periods were irregular, occurring as frequently as every 2 weeks or as infrequently as every 3 months. Associated with this was the progressive development of hirsutism. She sought medical care, which resulted in the administration of a 3-month

course of oral contraceptives leading to regular withdrawal bleeding. The irregular menstrual intervals returned with discontinuation of therapy.

The physical examination revealed a weight of 168 pounds and a height of 5 feet, 2 inches. Blood pressure was 136/94 mm Hg. The face was rounded and the back had a slight buffalo hump. There was evidence of acanthosis nigricans on the nape of the neck, moderate facial acne, and severe facial hirsutism, including the sides of the face, chin, and upper lip. Severe hair growth was also noted between the breasts. The abdomen was obese with no obvious masses. A male hair pattern with growth up to the umbilicus was present. Pelvic examination revealed a male escutcheon. The base of the clitoris, 8 mm in diameter, was not enlarged. The external genitalia and vagina were normal, and

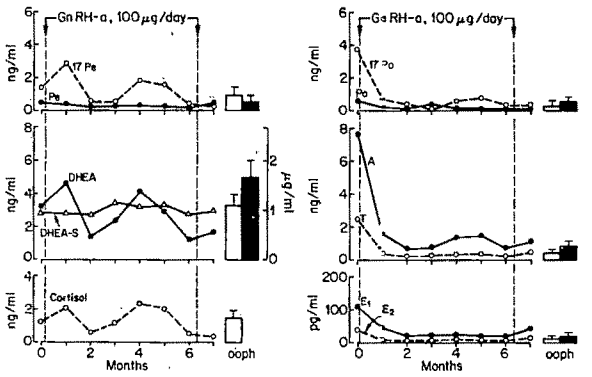

Fig. 3. Serum concentrations of Δ^5- and Δ^4-steroids, cortisol and estrogens before, during, and after gonadotropin-releasing hormone-agonist *(GnRH-a)* administration for 6 months. Values for dehydroepiandrosterone sulfate are expressed as micrograms per milliliter. *17Pe* = 17-Hydroxypregnenolone; *Pe* = pregnenolone; *DHEA* = dehydroepiandrosterone; *DHEA-S* = dehydroepiandrosterone sulfate; *17Po* = 17-hydroxyprogesterone; *Po* = progesterone; *A* = androstenedione; *T* = testosterone; E_1 = estrone; E_2 = estradiol.

the cervix was small. Palpation of the uterus was normal and no adnexal masses were felt.

The screening laboratory evaluation revealed the following: total testosterone, 4.1 ng/ml (range for normal women, 0.1 to 0.55 ng/ml); free testosterone, 110 pg/ml (1 to 6 pg/ml); dehydroepiandrostenedione sulfate, 1.2 μg/ml (0.6 to 2.5 μg/ml); 17-hydroxyprogesterone, 4.6 ng/ml (0.3 to 0.9 ng/ml); cortisol, 237 ng/ml (50 to 250 ng/ml); luteinizing hormone, 16 mIU/ml (5 to 25 mIU/ml); follicle-stimulating hormone, 9 mIU/ml (4 to 20 mIU/ml); and prolactin, 4.0 ng/ml (5 to 20 ng/ml). Administration of dexamethasone, 1 mg, at 11:00 PM resulted in a normal suppression of the fasting morning cortisol level to 10 ng/ml. The corresponding measurement of 17-hydroxyprogesterone was 4.9 ng/ml. In response to subsequent adrenocorticotropic hormone (Cortrosyn, 250 μg intravenously) stimulation, serum 17-hydroxyprogesterone decreased to 3.8 ng/ml.

Ultrasonographic evaluation of the pelvis failed to demonstrate an abnormality. An abdominal computerized tomographic scan revealed bilaterally normal adrenal glands, while the pelvic scan demonstrated a borderline enlarged right ovary and a fat-containing mass in the left adnexa. Retrograde femoral catheterization with selective venous sampling of the left and right adrenal and right ovarian veins was performed and no tissue abnormalities were noted on the fluoroscopic radiograms. Detection of the left ovarian vein was not possible.

On February 6, 1984, the patient underwent exploratory laparotomy with the finding of a benign cystic teratoma (6 by 7 cm) in the left ovary. The remainder of the ovary was elongated, approximately 3 by 5 by 2 cm. The right ovary was cylindrical in shape and measured 3 by 6 by 2 cm. The dermoid cyst was removed

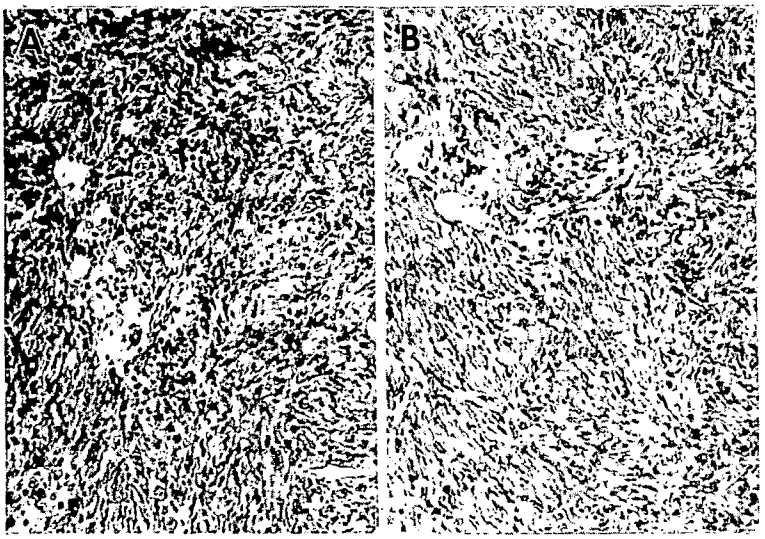

Fig. 4. Routine histologic section of both the right ovary *(a)* and left ovary *(b)* showing abundant and dense stromal cells. Note the focal collections of luteinized cells. (Hematoxylin and eosin. Original magnification ×10.)

from the left ovary, and a bilateral ovarian wedge resection was performed.

Resumption of menses and improvement of hirsutism did not occur during the 5 months after operation. Subsequently, treatment was initiated with a long-acting gonadotropin-releasing hormone agonist, D-His^6(ImBzl),Pro^{9}NEt-gonadotropin-releasing hormone, for 6 months. Two weeks after cessation of therapy, human menopausal gonadotropin was administered for induction of ovulation. A stepwise increasing dose regimen of human menopausal gonadotropin was used until adequate ovarian stimulation was achieved. Administration of three ampules per day for 4 days resulted in a rise of estradiol to 360 pg/ml. This dose was then maintained for another 4 days until serial ultrasound revealed two 14 mm follicles and an estradiol level of 1840 pg/ml. At this time human chorionic gonadotropin, 10,000 IU, was administered intramuscularly. Seven days later the serum progesterone level rose to 30 ng/ml, providing presumptive evidence of ovulation.

Material and methods

During selective venous catheterization, blood samples were obtained from each of the catheterized vessels and a peripheral vein for hormone analysis. Peripheral and left and right ovarian venous blood samples were also collected at the time of operation. Postoperative samples included those obtained consecutively for 4 days and at 1, 2, and 5 months after operation.

Six months after operation, treatment was initiated with the use of the gonadotropin-releasing hormone-agonist 100 μg/day, self-injected subcutaneously for 6 months. The medication was supplied by Ortho Pharmaceutical Corporation, Raritan, New Jersey. Blood samples were obtained before, at monthly intervals during, and at 1 month after cessation of gonadotropin-releasing hormone-agonist therapy. In addition, an endometrial biopsy specimen was obtained before and after treatment.

Serum levels of luteinizing hormone, follicle-stimulating hormone, androstenedione, testosterone, dehydroepiandrosterone, dehydroepiandrosterone sulfate, cortisol, estrone, estradiol, progesterone, 17-hydroxyprogesterone, pregnenolone, and 17-hydroxypregnenolone were measured by radioimmunoassay as previously described.[6-10] Reagents for the luteinizing hormone and follicle-stimulating hormone measurements were provided by the National Hormone and Pituitary Program. All luteinizing hormone and follicle-stimulating hormone measurements were converted to milli–international units per milliliter (second international reference preparation). Statistical evaluation was performed by analysis of variance with repeated measures, Student's paired *t* tests, and group *t* tests where appropriate.

Results

Selective venous catheterization. The peripheral, ovarian, and adrenal vein levels of steroids during the selective venous catheterization study were shown in Table I. Peripheral serum concentrations of androstenedione, testosterone, progesterone, and 17-hydroxyprogesterone were elevated above the ranges of values reported for normal women in the early follicular phase of the menstrual cycle. On the basis of ovarian–peripheral venous gradients, the right ovary appeared to actively secrete pregnenolone, 17-hy-

droxypregnenolone, 17-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, testosterone, estrone, and estradiol. The largest step-up of androgen in this vein was in androstenedione, which was fifteenfold, compared with that of testosterone and dehydroepiandrosterone, which were increased sevenfold and sixfold, respectively (Fig. 1). In addition, the secretion ratio of androstenedione to testosterone (ovarian–peripheral venous difference of androstenedione divided by that of testosterone) was 14:1. Of the progestins, 17-hydroxyprogesterone displayed the greatest step-up, exceeding that of pregnenolone and 17-hydroxypregnenolone by at least threefold. The ratio of ovarian to peripheral venous concentrations for estrone was 2.5 and for estradiol, 6.4.

A similar pattern of hormone secretion was found in the left adrenal venous sample. There was a minimal gradient of cortisol. The right adrenal vein exhibited marked adrenal–peripheral venous gradients for all steroids except estrone and estradiol. In particular large gradients of pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone, and cortisol were noted. Based on these findings, the pattern of hormone secretion by the left adrenal gland was very different from that of the right adrenal and was similar to that of the right ovary.

Intraoperative studies. Table II shows the levels of androgens found in the peripheral and ovarian venous samples obtained at operation. Based on the peripheral–ovarian venous gradients, the patterns of androgen secretion were similar for the two ovaries.

Response to operation. Circulating steroid hormone concentrations before, during, and after ovarian wedge resection are shown in Fig. 2. Mean ± SE values found in 10 women between 20 and 30 years of age who had undergone bilateral oophorectomy for gynecologic disease are shown for reference. In response to operation, there were immediate decreases of most Δ^5,- and Δ^4-steroids, cortisol, estrone, and estradiol, with a nadir reached on postoperative day 3. These included decreases of elevated androstenedione, testosterone, and 17-hydroxyprogesterone levels into the range of values for normal women. Serum levels of pregnenolone and progesterone were unaltered. Shortly after these declines, progressive rises were observed for all suppressed steroids, which resulted in the return of concentrations to preoperative values within 4 weeks after operation. During the next 4 months, circulating steroid levels remained unchanged.

Response to gonadotropin-releasing hormone-agonist. As shown in Fig. 3, daily administration of a gonadotropin-releasing hormone-agonist had a significant suppressive effect on all Δ^4-steroids, estrone and estradiol. By 2 months of treatment, the circulating levels of these were similar to those of surgically castrated women. In contrast, the Δ^5-steroids and cortisol were not affected by the gonadotropin-releasing hormone-agonist. The decremental change of Δ^4-steroids and estrogens in response to the gonadotropin-releasing hormone-agonist was more pronounced than that observed after ovarian wedge resection. Inhibition of ovarian steroidogenesis persisted for the 6 months of gonadotropin-releasing hormone-agonist administration and for 1 month thereafter.

Basal serum luteinizing hormone and follicle-stimulating hormone levels were 13 and 9 mIU/ml, respectively. These concentrations remained constant throughout the course of gonadotropin-releasing hormone-agonist treatment as the mean (±SE) value for luteinizing hormone was 14.7 ± 0.7 mIU/ml and for follicle-stimulating hormone, 8.7 ± 0.4 mIU/ml.

Pathologic findings. Ovarian tissue from wedge resection was firm and yellow-tan in appearance. Histologically, the tunica albuginea was thickened and follicles were seen in various stages of development. In both ovaries stromal cells were abundant, dense, and spindle-shaped without nuclear abnormalities (Fig. 4). Focal collections of luteinized cells were also noted. Reactive luteinization of tissue adjacent to the teratoma was not found. In the right ovary there was an involuting corpus luteum.

Tissue specimens obtained at endometrial biopsy revealed hyperplastic endometrium before gonadotropin-releasing hormone-agonist administration. After 6 months of treatment, repeat biopsy demonstrated atrophic endometrial glands and stroma.

Comment

On the basis of the marked elevation of the testosterone level (4.1 ng/ml) in the screening blood sample, the normal suppression of serum cortisol with dexamethasone administration, and the limited response of 17-hydroxyprogesterone to adrenocorticotropic hormone administration, it was concluded during the patient's initial evaluation that she had either an androgen-secreting tumor of the ovary or of the adrenal gland or ovarian hyperthecosis. These conditions are generally associated with testosterone elevations of this magnitude, particularly in the absence of hypercortisolism or a 21-hydroxylase defect of the adrenal glands.

Ultrasonic evaluation of the pelvis was not helpful in localizing the site of the abnormal hormone secretion. Computerized tomographic scan of the abdomen and pelvis suggested the source may have been the left ovary. Retrograde venous sampling and measurement of hormonal gradients between the peripheral and adrenal and ovarian veins were not helpful because of the inability to catheterize the left ovarian vein. This difficulty was surprising since entry of this vessel into the left renal vein is usually easy to identify.[11] The fact that the profile of hormones found in the left adrenal vein was similar to the pattern observed in the right ovarian but not the right adrenal vein suggests that the left ovarian vein likely had an aberrant connection with the left adrenal vein. This conclusion is supported by the absence of a step-up of cortisol in the left adrenal sample and the finding of similar androgen levels in the left and right ovarian venous samples obtained at operation.

We have reported the use of retrograde catheterization to localize androgen-secreting tumors on several occasions and have had excellent success with this method.[11] The present results indicate that this technique has potential limitations because of the variable anatomy of the venous systems draining these glands.

At the time of operation two ovarian lesions were observed, a benign cystic teratoma and ovarian hyperthecosis. Although both lesions have been associated with marked androgen excess, it is likely the hyperthecosis was responsible in this patient since removal of the ovarian tumor was associated with only a transitory reduction of androgens.

The implied functional nature of this disorder suggests that successful therapy might be achieved by suppression of androgen production instead of extirpation of the ovary. However, previous attempts at medical management have been disappointing and the current recommended treatment remains either ovarian wedge resection or bilateral oophorectomy. Wedge resection has been used with satisfactory results in patients with the mild form of hyperthecosis as characterized by normal or slightly elevated testosterone levels. In five patients with mild disease, ovarian wedge resection resulted in a return of cyclic menses in all and pregnancy in one.[12] The highest circulating concentration of testosterone in these patients was 0.72 ng/ml. Unfortunately most studies have not included long-

term follow-up and therefore ultimate outcome has been undeterminable. Women with higher serum testosterone levels are more refractory to this type of treatment. Some reports have documented initial ovulatory responses after operation, which have not persisted over time.[5] In most instances, the serum testosterone level ranged between 1 and 3 ng/ml.

Our patient exhibited severe androgen excess and, similar to the experience of others, reverted to her preoperative condition soon after wedge resection. From these data it would appear that the level of testosterone correlates not only with the degree of clinical symptoms but also with the response to surgical therapy. The transitory fall of both Δ^5- and Δ^4-steroids at the time of operation presumably reflected the impact of anesthesia and operation on adrenal steroid secretion coupled with an effect of wedge resection on ovarian steroidogenesis.

Previously we have shown that the administration of a gonadotropin-releasing hormone-agonist to women with polycystic ovary syndrome and ovulatory women with endometriosis resulted in complete suppression of ovarian steroid secretion.[13] The unique ability of this drug to cause a medical oophorectomy compelled us to implement its use in our patient. Consistent with our earlier experience, profund reductions of ovarian androgen, estrogen, and progestin secretion were observed. After 1 month of treatment, serum androstenedione and testosterone levels approximated concentrations seen in normal premenopausal women and by 2 months both androgens were in the range seen in castrated women. That this response was somewhat delayed compared with that seen in women with polycystic ovary syndrome may reflect the severity of disease as the pretreatment circulating levels of androstenedione and testosterone far exceeded those seen in patients with polycystic ovary syndrome. On the other hand, measurements of these hormones at 1 month as well as at 4 and 5 months of treatment may have reflected spontaneous adrenal activity that contributed to increased serum concentrations as simultaneous increases were noted for cortisol and the Δ^5-steroids dehydroepiandrosterone and 17-hydroxypregnenolone. In general, adrenal androgens were not significantly altered by gonadotropin-releasing hormone-agonist therapy.

Clinically, the patient did not perceive any change of hair growth pattern during gonadotropin-releasing hormone-agonist treatment. This is not surprising since severe hirsutism has typically been slow to respond to a variety of therapeutic measures including administration of antiandrogens such as cyproterone acetate. The duration of ovarian androgen suppression was also only 4 months and the facial hair growth cycle exceeds at least 6 months. In comparison, the reduction of estrogens was probably responsible for conversion of a hyperplastic endometrium to an atrophic one.

One of the major problems confronting our patient was the inability to conceive. The successful ovulation induction was achieved in our patient by human menopausal gonadotropin administration in the immediate posttreatment period suggests that elimination of the enormous amounts of intraovarian androgen by the gonadotropin-releasing hormone-agonist may have been instrumental. Previous studies have shown that local androgen production interferes with follicular growth and development. In hypophysectomized immature female rats the ovarian weight response to diethylstilbestrol is inhibited by human chorionic gonadotropin. This effect is reversed by administration of an antiandrogen. In the same rat model, granulosa cell death and follicular attrition of medium-sized follicles may be accelerated by the addition of dihydrotestosterone or human chorionic gonadotropin treatment. These findings support the observation in humans that hyperandrogenic ovaries are often associated with multiple follicular cysts, which are degenerative and lack healthy-appearing oocytes.[14]

Similar to the reports of several prior studies,[4, 5] circulating luteinizing hormone levels were normal in our patient, suggesting greater responsiveness of ovarian stromal cells to luteinizing hormone relative to an absolute increase in number and/or enhanced sensitivity of individual cells. Another mechanism could be inferred from the ovarian response to the gonadotropin-releasing hormone-agonist. Since we have demonstrated previously a marked suppression of bioactive luteinizing hormone concentrations in women with both endometriosis and polycystic ovary syndrome treated with a gonadotropin-releasing hormone-agonist,[15] it was likely that bioactive luteinizing hormone was suppressed in our patient during therapy, thereby accounting for the reduction of ovarian androgen. These data also support a primary role for luteinizing hormone in the generation of excess ovarian androgen in this syndrome.

With the dominant ratio method, the preferred steroidogenic pathway of these hyperthecotic ovaries was pregnenolone → 17-hydroxypregnenolone → 17-hydroxyprogesterone → androstenedione → testosterone (Fig. 1). These results differ from those of Abraham and Buster,[16] who reported two cases of hyperthecosis and normal circulating androstenedione levels. They proposed a selective blockade of $\Delta^4 C_{17\text{-}20}$ desmolase to account for the normal serum androstenedione values and a preferential pregnenolone → 17-hydroxypregnenolone → dehydroepiandrosterone → androstenediol → testosterone pathway to explain the elevated serum testosterone concentrations. In our patient there were step-ups of 17-hydroxypregnenolone → dehydroepiandrosterone and 17-hydroxyprogesterone → androstenedione in the ovarian veins, indicating intact $C_{17\text{-}20}$ desmolase activity. In addition, we

were unable to establish significant ovarian cortisol secretion, as noted by Abraham and Buster,[16] compared with the large right adrenal–peripheral venous gradient for this hormone.

In summary, this case report has demonstrated the dramatic suppressive effect of a gonadotropin-releasing hormone-agonist on ovarian steroidogenesis and androgen production in severe hyperthecosis. The lack of symptomatic improvement of hirsutism was probably related to the short interval of treatment and suggests the need for more prolonged therapy in these patients. These data indicate that for the first time a method is available that can eliminate the massive androgen secretion seen in patients with this disease without a need for bilateral oophorectomy. It is likely that the androgen excess in these patients could be controlled by this method until childbearing is completed before the performance of ovarian extirpation.

Discussion

Dr. Charles D. Kimball, Seattle, Washington. I am very pleased to have the opportunity to comment on Dr. Judd's article. I hope to raise a few logical questions and suggest some possible answers.

This report is an excellent example of a case study that integrates basic science research with clinical practice of medicine. For more than a decade Dr. Judd and his colleagues have made impressive and significant contributions to our understanding of androgenizing endocrine disorders of women. This report clearly demonstrates the fact that complete but reversible castration can be accomplished by physiologic rather than surgical or pharmacologic means, which in my view is a new peak in therapeutic achievement. It also shows that exogenous gonadotropes can rehabilitate ovaries that are advanced in hyperthecosis.

The elevated androgenic production by the theca cells of this patient beginning 12 years after menarche and shortly after marriage raises interesting and exciting questions for future research regarding the molecular mechanisms that triggered the prolonged and persistent luteinizing hormone stimulation of the androgenic hormones. It also opens the way for consideration of the role of opioid and catecholamine hormones in modulating the periodic oscillatory frequency of gonadotropin-releasing hormone output by hypothalamic cells and the adjacent neurosecretory cells that produce β-endorphin and dopamine. It appears that the ovarian cycling that was normal in this patient before the onset of virilization got "stuck" in the "groove" and repeated the endorphin-controlled gonadotropin-releasing hormone pulse frequency that evoked excessive luteinizing hormone production.

There are also questions about the enzyme mechanisms that demethylate and aromatize androgens to estrogens. Failure of this enzyme mechanism would result in a vicious feedback cycle whereby high steroid-dependent opioid hormone levels sustain the prolonged and excessive gonadotropin-releasing hormone–luteinizing hormone–C^{19}-steroid output and thus prevent normal maturation and lysis of the corpus luteum with collapse of the mutually dependent opioid-steroid structure.

There are interesting questions regarding the function of catecholamines, especially dopamine, in the ovulation cycle of this patient. Numerous reports have indicated that β-endorphin and dopamine are secreted in counterbalance with each other in the hypothalamic-hypophyseal portal system that regulates prolactin, follicle-stimulating hormone, and luteinizing hormone production.

Elevated β-endorphin serum levels have recently been reported in amenorrheic, hirsute, hyperandro-

genic, obese women.[1,2] Serum β-endorphin and its precursor polypeptide β-lipotropin are split by enzymatic cleavage from the precursor protein proopiomelanocortin in response to physiologic stress. One wonders if a stressful marriage might have produced chronic elevation of β-lipotropin and anomalous cleavage by enzymes that liberate melanocyte-stimulating hormone as well as excess β-endorphin. We have two ready clues to this possible mechanism. The earlier article by Judd et al. on familial hyperthecosis indicates a genetic tendency (see reference 5 of article). The other is the presence of acanthosis nigricans, indicating a melanocyte-stimulating hormone effect on pineal hormones that also regulate estrus and the mating season. In other words, this patient may not have been sexually ready, which many women equate with stress.

Many intriguing lines of basic science investigation are opened by case studies such as this, which demonstrate important benefits from integrating clinical research and clinical practice.

Dr. Frederick Hanson, Sacramento, California. With the use of feralin acetate for endometriosis, we are concerned with osteoporosis, and some of the bone densitometric studies in that part of our protocol seem to indicate that this is a potential problem. Did you look at this in this woman, as it will be a problem with use of these drugs? If a patient does not desire pregnancy, what do you see as long-term therapy? I assume rebound will occur and she will be right back where she was as soon as the agonist is stopped. Since we cannot use these drugs on a long-term basis what are her other options? She cannot be pregnant all the time either.

Dr. Simon Henderson, San Francisco, California. I would like to ask just one or two questions and first of all just start with my assumption that this was essentially a patient who was trying to become pregnant but was also a research patient and that is why the analogue was given. I understand also that you suspected an ovarian mass, and maybe that was why you performed the wedge resection. I was not totally clear from all of this what your plan of practical management would be for these patients in the future. We do have other modalities such as using menotropins (gonadotropin), without many of the procedures performed in this patient. Also clomiphene sometimes works in these patients. I would like your comments as to the basic core management of these patients in the future.

Dr. Jack Hallatt, Los Angeles, California. We have made a striking observation that there is a correlation between the incidence of dermoid cysts and polycystic ovary syndrome. Now, is this a true relationship or is it just anecdotal and coincidental?

Dr. Judd (Closing). Dr. Kimball addressed the issue of the mechanism by which this patient had elevated androgen levels. It is very clear that the elevation was produced by the gonadotropins. This is based on the observation that when we suppressed the gonadotropins the androgen level decreased. However, the gonadotropin levels were repetitively measured in the normal range. So either she has a group of cells that are hypersensitive to gonadotropins or she has a group of cells that have developed on their own and will now be sustained by normal gonadotropin levels.

Dr. Hanson raised a question in regard to long-term use of the gonadotropin-releasing hormone analogue. In a patient with severe hyperthecosis who is trying to become pregnant, it is very likely that the only way this can be accomplished is by suppression of ovarian function. There is no reason in a case such as this that long-term suppression should not be used. Also there is absolutely no reason not to administer hormone replacement until the patients are ready to have children. Only after the family is completed would ovarian removal need to be considered. Until now this has not been possible. Use of the analogue provides us with a way of temporizing. As to the issue of long-term analogue use in osteoporosis, I do not think this is a problem with severe hyperthecosis. In this case there is absolutely no reason not to give estrogens and progesterone during analogue administration.

Dr. Henderson brought up the concept that there are other ways of treating this disorder. I would disagree with you, Dr. Henderson. The track record in the literature is that wedge resection, clomiphene, Pergonal, and any form of therapy other than bilateral oophorectomy have not been adequate to treat this hyperandrogenism. Consequently, in treating women who have androgen levels in the male range, other forms of therapy will have to be realized. This is the first time there is an alternative other than surgical oophorectomy.

Dr. Hallatt brought up the very interesting question of the possible relationship between dermoid cysts and polycystic ovary syndrome. The fact is that there is a potential relationship. Dermoids and a variety of other tumors of the ovary have been associated with increased androgen production. The tumors themselves do not seem to produce the androgens. What happens is that the tumors are probably producing a human chorionic gonadotropin–like substance. At the local level they stimulate stromal hypertrophy and luteinization of the stroma immediately adjacent to the tumor. This stroma produces the increased androgen levels, as has been shown in patients with dermoid cysts. As ovarian androgen production is increased, it is possible that polycystic ovarian disease develops We do not think this happened in our patient for two reasons: First, the hyperthecosis was bilateral, and this has never been described with a tumor. The stromal hyperplasia has been described only in the immediate vicinity of the tumor. Second, we removed the tumor and the condition persisted.

Chorionic villus sampling: Experience of the first 1000 cases

W. A. Hogge, M.D., S. A. Schonberg, M.D., and M. S. Golbus, M.D.,
San Francisco, California

Chorionic villus sampling has become widely accepted as a first-trimester alternative to amniocentesis for the prenatal detection of genetic disorders. Our experience with 1000 consecutive cases suggests that spontaneous abortion following the procedure is related to the gestational age at which it is performed, and the rate is acceptably low (3.8%) when the procedure is performed from the ninth through the eleventh menstrual week. Later complications include chorioamnionitis (0.6%) and delayed rupture of membranes and/or oligohydramnios (0.8%). A discrepancy between the villus karyotype and that of the fetus was found in 1.7% of cases and most commonly consisted of mosaicism in the villus sample for a chromosomal abnormality that was not found in fetal samples. We conclude that although chorionic villus sampling appears to be an acceptably safe and reliable procedure, further investigation is needed before this first-trimester technique is widely utilized as an alternative to amniocentesis. (AM J OBSTET GYNECOL 1986;154:1249-52.)

Key words: Chorionic villus sampling, complications, karyotype, amniocentesis

In the less than 5 years since the widespread introduction of chorionic villus sampling as a clinical diagnostic tool, the procedure has emerged as a first-trimester alternative to amniocentesis. A number of previous reports based on small numbers of patients with limited follow-up have indicated the feasibility of chorionic villus sampling and have provided some preliminary information on the safety, efficacy, and reliability of sampling in the first trimester.[1-3] Our experience with the first 1000 consecutive chorionic villus samplings performed at the University of California, San Francisco, is presented to more specifically identify those factors that influence the safety and reliability of chorionic villus sampling.

Methods

The chorionic villus sampling program at the University of California, San Francisco, has been previously described.[3] Briefly, sampling was performed between 8 and 12 weeks from the last menstrual period with the use of a 16-gauge Intracath (Deseret Co., Sandy, Utah). The catheter was directed transcervically under sonographic guidance to a location within the villus of the chorion frondosum. Villus samples of 5 to 50 mg (wet weight) were obtained by suction aspiration. For cytogenetic analysis, long-term cultures were established in duplicate in Chang's "closed" medium (Hana Biologics, Berkeley, California). All procedures were performed under a protocol approved by the University of California, San Francisco, Committee on Human Research.

Results

Table I outlines the indications for chorionic villus sampling and the number of abnormalities found. As is the case for amniocentesis, over 90% of the procedures were performed for advanced maternal age. The incidence of chromosomal abnormality (4.2%) in this group is appreciably higher than that found in the second trimester (2.5%).[4] This difference indicates that a significant proportion of chromosomally abnormal fetuses are lost before the sixteenth week of pregnancy.

The categories of chromosomal abnormalities are given in Table II. As expected, the most common finding is autosomal trisomy, accounting for almost 50% of the abnormalities detected. A disturbing finding is the 1.2% incidence of mosaicism, which represents almost one fourth of the abnormalities seen. A detailed analysis of these cases is shown in Tables III and IV. Most of these karyotypes would be of clinical significance if detected at amniocentesis. With the exception of the one case of mosaicism for trisomy 21, which almost certainly represented a low level of maternal cell contamination, none of the villus karyotypic abnormalities were confirmed by amniocentesis or fetal tissue studies. Despite the small number of cases, it is notable that 33% of the patients with villus chromosomal mosaicism who intended to continue their pregnancies spontaneously aborted. Only one of these patients has completed her pregnancy at the time of this writing, and she was delivered of a 3260 gm healthy male infant.

There were two additional cases in which a discrepancy was noted between the villus karyotype and that of the fetus. These two instances of chromosomal aneu-

ploidy (45,X in one case; 47,XX, + 16 in the other) were not confirmed on fetal skin samples (46,XY and 46,XX, respectively) obtained following pregnancy termination. Unfortunately, no placental tissue was submitted for analysis.

Complications. Immediate complications of chorionic villus sampling are uncommon. An adequate sample was obtained on the first visit in 97.4% of the cases. There were only two cases of rupture of the amnion at the time of the procedure. We consider culture failure as an immediate complication, and it is likewise uncommon, occurring in less than 1% of the cases.

The major short-term complications of chorionic villus sampling are pregnancy loss and diagnostic error. In addition to those cases noted above, there were three cases of diagnostic error caused by maternal cell contamination. All three errors were detected and corrected prior to 20 menstrual weeks. The overall error rate (both false positive and false negative results) was 1.7%.

Details of the pregnancy losses are given in Table V. Spontaneous abortion followed the procedure in 51 cases (5.4%), three of which were attributed to chorioamnionitis. Another three cases of acute chorioamnionitis were diagnosed after 20 menstrual weeks.

There were three instances of delayed rupture of the fetal membranes, each occurring approximately 8 weeks after the procedure. In another five cases, severe oligohydramnios was noted on sonograms obtained between 16 and 20 weeks' gestation. Despite the finding of almost a complete lack of amniotic fluid, there was no clinical history to suggest overt rupture of the membranes or leakage of amniotic fluid. No gross fetal anomalies were noted in these pregnancies, which either spontaneously aborted (four cases) or were electively terminated (two cases).

In Table VI the 950 pregnancies meant to continue are divided on the basis of gestational age at the time of chorionic villus sampling. The incidence of spontaneous abortion in those patients sampled from 9 menstrual weeks to 11 weeks 6 days was only 3.8%. On the basis of relatively small numbers, patients having chorionic villus sampling prior to and after this period had an appreciably higher loss rate (12.9% and 17.1%, respectively).

Translocation—unbalanced	6
Translocation—unbalanced (de novo)	3
Chromosomal fragment	1
Total	50

Long-term complications of chorionic villus sampling theoretically could include fetal anomalies, placental accidents or dysfunction, and intrauterine growth retardation. Approximately 50% of those pregnancies that were intended to be continued have now resulted in delivery. Four infants have been born with congenital anomalies: one with Goldenhar syndrome (hemifacial microsomia), one with severe craniosynostosis resulting in a cloverleaf skull deformity, one with achondroplasia (both parents have normal stature), and one with bilateral polydactyly. None of these anomalies appears to be related to the prenatal diagnostic procedure, and this incidence is no different from what would be expected in the general population. There have been two cases of placenta previa and no instances of intrauterine growth retardation, although ascertainment is not yet complete.

Comment

Chorionic villus sampling has rapidly gained wide acceptance as an alternative to amniocentesis for the prenatal diagnosis of genetic disorders. Although it is being performed in many centers throughout the world, only preliminary evidence is available regarding the safety, efficacy, and reliability of this new procedure. Based on our experience with 1000 samplings, it appears that chorionic villus sampling is acceptably safe and reliable. However, several issues are raised that must be further evaluated before chorionic villus sampling can be widely applied for prenatal diagnosis.

There is a significant incidence (1.7%) of discrepancy between the apparent karyotype of the villi and that of the fetus. A small portion of this error rate is attributable to maternal cell contamination, which appears to be related to experience. With the use of meticulous techniques for removing maternal cells from the villus samples, this source of error should be small. The remainder of the cases appear to represent true mosaicism within the placenta. That this finding is biologic, and not simply an artifact of long-term culture, is supported by studies of spontaneous abortion material in which mosaic trisomies occur in a significant proportion of cases.[5] These abortion analyses are commonly done on extraembryonic tissue, not on fetal material, and

they suggest that the rates for aneuploidy in spontaneous abortion would be lower if fetal tissue only were evaluated. The significance of chromosomal abnormality limited to extraembryonic tissue is not yet clear. A report by Kalousek and Dill[6] suggested there may be an association between chromosomal mosaicism in the placenta and intrauterine growth retardation. Because of the uncertain significance of mosaicism in the villus sample, we offer these patients a follow-up amniocentesis. The results of the amniotic fluid cell analysis have been normal in all cases to date, and there are a number of ongoing pregnancies that should provide some preliminary information to help answer these questions.

Previous reports from this institution have suggested that infection may be a small but important aspect of the complications of chorionic villus sampling.[7,8] There remains a significant rate of chorioamnionitis (0.6%), and, as shown previously, there is a clinical history to suggest infection in a large portion of patients having spontaneous abortion after chorionic villus sampling.[7]

A striking finding in this study is severe oligohydramnios in six patients, none of whom had a history of fluid leakage. This suggests that chorionic villus sampling may in some way damage the chorion and/or amnion and may alter the normal fetomaternal fluid dynamics. If to these six cases are added those with both immediate and delayed rupture of the amnion, there is a relatively high incidence (1%) of complications related to membrane damage. However, these complications can occur in pregnancies that have not had prenatal testing, and only with a controlled study can the true incidence related to chorionic villus sampling be determined.

Although there does appear to be a small risk of later complications related to chorionic villus sampling, our spontaneous abortion rate of 3.8% is not different from those rates reported in sonographically normal pregnancies of comparable gestation and maternal age.[9,10] We must emphasize that this low rate occurs in those cases in which chorionic villus sampling was done after 8 menstrual weeks and prior to 12 weeks.

In summary, our experience suggests that chorionic villus sampling is an acceptably safe and reliable method of prenatal diagnosis. However, the questions raised regarding infection, membrane damage, and placental mosaicism must be answered. The ongoing National Institutes of Health collaborative study of both chorionic villus sampling patients and control patients undergoing amniocentesis should provide these answers.

The technical assistance of Alison Porter-Stein and Timothy Tomashek, the genetic counseling assistance of Joan Hogge and Roberta Tung, and the sonographic assistance of Antoinette Golbus and Helen Gammon are appreciated. Without them, this program would not be possible. Dr. Gary Simpson kindly provided ongoing discussion, suggestions, and technical assistance in the development of the program.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Detection of preterm labor by ambulatory monitoring of uterine activity for the management of oral tocolysis

Michael Katz, M.D., Pamela J. Gill, R.N., M.S.N., and Roger B. Newman, M.D.
San Francisco, California

A study to evaluate whether ambulatory tocodynamometry at home could enhance the management of oral tocolysis was performed. On discharge from the hospital, after completing parenteral tocolysis, 60 patients received a lightweight tocodynamometer, designed for storage and transmission of uterine activity data. Sixty additional contemporary patients, who were matched for maternal age, parity, and risk factors, served as a control group. In addition to instructions regarding self-detection of recurrent preterm labor, monitored patients recorded uterine activity for ≥200 min/day and then transmitted the data to the study center. Tocolytic dosage was adjusted to maintain mean uterine contraction frequency of <4/hr. Persistent uterine contractions of ≥4/hr lead to in-hospital evaluation for recurrent preterm labor. The results indicate that the monitored group had a lower incidence of preterm births mostly because of a decrease in the proportion of patients with failed tocolysis. It is suggested that surveillance of uterine activity at home during oral treatment for preterm labor may be instrumental in improving perinatal outcome in high-risk patients. (Am J Obstet Gynecol 1986;154:1253-6.)

Key words: Labor, preterm, oral tocolysis, tocodynamometry, perinatal outcome, management, home

Currently, the management of parenteral tocolytic therapy relies mostly on uterine activity response to treatment, a response that is best evaluated by external tocodynamometry. Once successful in achieving adequate control of contractions, parenteral tocolysis is replaced by an oral maintenance dose.[1-3] However, the effect of this tocolytic regimen on uterine activity at home can no longer be objectively evaluated even though adjustments in treatment may be required. It is thus conceivable that if means to follow uterine activity response to oral tocolysis at home were available, proper adjustments in treatment could be made and thereby enhance the effectiveness of tocolysis. If in spite of these adjustments oral tocolysis can no longer control uterine activity, home monitoring could help make the early diagnosis of recurrent preterm labor. The following study evaluated whether ambulatory tocodynamometry at home could contribute to the management of patients who were receiving oral tocolysis after their initial preterm labor episode had been controlled by parenteral in-hospital therapy.

Material and methods

One hundred twenty patients who completed their initial in-hospital course of parenteral tocolysis and were about to be discharged home with oral medication were recruited into the study after signing the appropriate consent forms. The initial diagnosis of preterm labor was made whenever persistent and regular uterine contractions were associated with progressive cervical dilation and effacement before 36 completed gestational weeks. The recurrence of such episodes in these patients was termed recurrent preterm labor. Gestational age was determined by considering the last menstrual period, uterine size, sonography, and neonatal evaluation. A delivery before 36 completed weeks' gestation is reported here as preterm. A delivery before 36 weeks' gestation that was the result of a condition such as severe preeclampsia or fetal death is reported here as an indicated preterm birth.

Sixty of the patients (group 1) received a lightweight uterine activity monitoring device designed for ambulatory recording, storage, and transmission of uterine activity data.[4] Because of the limited number of monitoring devices, assignment to the monitored group was not at random but rather on an availability basis. All contemporary patients who were eligible for home monitoring, but for whom no monitor was available, formed a pool from which 60 control subjects (group 2) were selected to match the following variables in group 1: (1) maternal age (±5 years), (2) parity, and (3) risk factors (for instance, multifetal gestations, previous preterm births). Only patients who started prenatal care at or before 12 weeks' gestation and who were cared for by their private obstetricians throughout pregnancy were included. Patients who were transferred into this institution with recurrent preterm labor

Previous preterm birth				
1	18	30	26	43
>1	8	13	5	8
Diethylstilbestrol, cerclage, uterine anomaly	6	10	4	7
No apparent risk factor	8	13	16	27

and then delivered before term and those who received tocolytics not in compliance with the earlier described definition of preterm labor were not included in the study. In spite of attempts at exact matching, there were not enough multifetal gestations available for the control group, and these were therefore substituted by patients with other risk factors for preterm labor and delivery. As shown in Table I, the monitored group included a somewhat larger proportion of patients at high risk of preterm birth. On discharge from the hospital each study patient in both groups received instructions about the following: signs and symptoms of recurrent preterm labor,[5, 6] techniques of self-palpation for excessive contractions,[5, 6] and techniques of determining pulse rate. Patients were also instructed to remain at bed rest except for limited ambulation (meals and the bathroom).

The 60 monitored patients in group 1 recorded uterine activity three or four times daily for a cumulative total of 200 min/24 hr. The stored data were then transmitted daily, via the telephone, to receiving tocographs, which were located in the study center. Each transmission lasted 6 to 8 minutes and verbal feedback about the findings was given to the subjects. Additional transmissions were done if so desired by the investigators and an open emergency line was available 24 hours a day for monitored patients who wished to transmit additional data. Only contractions lasting more than 35 seconds were included in the analysis.[7] Shorter-duration contractions, most of which were of the low-amplitude, high-frequency type ("Alvarez waves"), were ignored. If four or more contractions per hour were seen, oral tocolysis was increased (dosage and/or frequency) to maintain uterine activity at a frequency of ≤3/hr while at bed rest. If the patients' pulse rates, just before taking the next dosage, exceeded 110 bpm and uterine activity persisted at four or more contractions per hour the patients were instructed to come for in-hospital monitoring and evaluation to rule out recurrent preterm labor. The choice of these uterine activity criteria was based on previous studies concerning in-hospital as well as ambulatory tocodynamometry in pregnant patients.[7, 8] After admission to the hospital of a monitored subject, if additional regular uterine activity along with cervical changes could be documented, parenteral tocolysis for recurrent preterm labor was administered. On completion of this treatment, patients were again discharged home to continue home monitoring as before.

Dosage schedules of parenteral and oral tocolytic medications of the two β-sympathomimetics, ritodrine and terbutaline, that were used in this study are described in detail elsewhere.[1-3] Briefly terbutaline (2.5 to 5 mg) or ritodrine (10 to 20 mg) tablets were given every 2 to 6 hours. In group 2 (controls) the fixed dose to be taken at home was the one that controlled contractions during the last 24 hours before discharge, while in the monitored group dosage schedule was adjusted as described above. Patients were instructed to contact their provider if the frequency of contractions was ≥4/hr or if the pulse rate exceeded 110 bpm just before taking the next dose. All patients who were having either objective (monitored) or subjective (control, by palpation) evidence of excessive uterine activity were admitted to the hospital for evaluation of recurrent preterm labor. The in-hospital management of all patients from both groups was identical except for the fact that control patients did not receive a home monitoring device on discharge from the hospital. Oral tocolysis was discontinued at 37 weeks' gestation, and since most practitioners would not initiate parenteral tocolysis after 36 gestational weeks, home monitoring was stopped at that point. The variables relating to pregnancy course and outcome were compared between the groups by the unpaired *t* test and χ^2 analysis where appropriate. The results are expressed as mean ± SD.

Results

As shown in Table II, maternal characteristics were quite similar in both groups. The somewhat insignificant increased mean number of prenatal visits for the monitored group reflects the fact that more of them had longer gestations. Preterm labor was diagnosed at 28.2 ± 2.5 weeks' gestation in group 1 (monitored) patients and at 29.5 ± 2.7 weeks' gestation for group 2 controls. Oral tocolysis for each group was started approximately a week later (group 1, 29.1 ± 3 weeks;

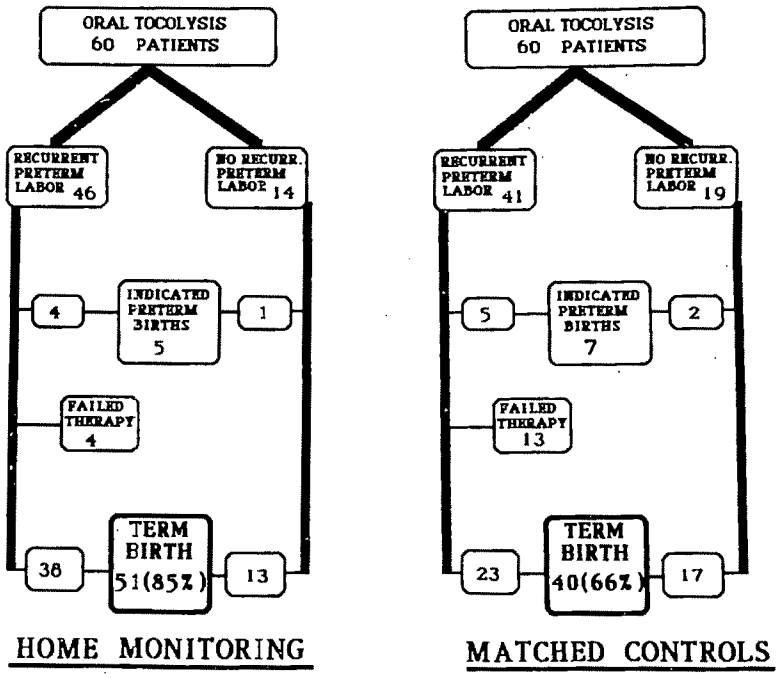

Fig. 1. Pregnancy course and outcome for the study sample.

group 2, 30.7 ± 2.9 weeks), and the mean duration of home monitoring for group 1 patients was 6.4 ± 3.2 weeks. The course and outcome of pregnancies for both groups are illustrated in Fig. 1.

Forty-six (77%) of group 1 (monitored) patients had a total of 83 episodes of recurrent preterm labor (1.8 ± 1.2 episodes per patient) as compared with 41 (67%) of group 2 controls who had 59 episodes of recurrent preterm labor (1.4 ± 1 episodes per patient). Neither the proportion of patients with recurrent preterm labor nor the incidence per patient was significantly different between the groups.

The overall proportion of preterm births was significantly smaller for group 1 (15%) as compared with group 2 controls (34%) ($p < 0.05$). This difference was due to the higher incidence of failed therapy among controls as compared to that of monitored patients (22% versus 7%, $p < 0.05$). The mean time gained in utero from the time that treatment for preterm labor was initiated was significantly longer for group 1 (monitored) patients (7.4 ± 3 weeks) than for group 2 controls (4 ± 1.2 weeks).

Table II. Clinical characteristics of study patients

	Monitored	*Matched*
Age (yr)	26.2 ± 7.5	27.8 ± 7.0
No. of multiparous/No. of primiparous	37/23	35/25
Prenatal care started (wk)	10.0 ± 3.0	9.4 ± 2.7
Bishop score at entry	4.2 ± 2.9	3.9 ± 2.5
Visits/patient (n)	9 ± 3	7 ± 4

Comment

Previous investigators have demonstrated that maintenance of tocolysis by oral administration of β-adrenergic agonists resulted in a significantly decreased incidence of recurrent preterm labor,[3] a significant prolongation of pregnancy,[2] and an improved perinatal outcome.[2] However, unlike other out-of-hospital treatments, such as glucose monitoring of insulin-dependent diabetic women, the management of oral tocolysis could not, up until now, rely on the target organ's response to treatment. In the absence of means to objectively monitor uterine activity during oral tocolysis at home, alternative approaches had to be used. These include prescribing the oral dosage schedule that successfully maintained uterine quiescence during the last 24 hours before discharge,[1] adjustment of treatment to maintain a mild sustained tachycardia 24 hr/day,[1] or reliance on the patient's perception of uterine activity.[5, 6] It seems though that in light of the reported cardiac tachyphylaxis to β-sympathomimetics[9] as well as the relatively limited accuracy of self-perception of uterine activity[10] these approaches are not likely to be successful. Recognizing the need for objective monitoring of uterine activity at home, Zahn,[11] more than a decade ago, was the first to experiment with home ambulatory tocodynamometry for the management of oral tocolytic therapy, but his work was not followed by others.

Determination of the appropriate oral tocolytic maintenance dose while the patient is still in the hospital

may often be inaccurate because of the many unknown factors that are associated with the home environment and may affect uterine activity. It is therefore reasonable to believe that adjustments in dosage schedule may be needed after discharge. In order to carry out these adjustments, preliminary studies to determine the frequency of uterine activity in normal and abnormal pregnancies were performed at an earlier stage.[7] These studies have shown that the criteria for excessive uterine activity that were used in the current study would establish an accurate diagnosis 80% of the time. Therefore the likelihood of overtreatment (placebo effect) in the current study is estimated at 20%. This rate of excessive treatment is well within the range reported by others.[1] On the other hand, the likelihood of significant cervical dilation and effacement when contraction frequency is ≤3/hr is minimal.[7]

An additional potential concern is the adjustment of medications that have the potential for causing adverse cardiovascular side effects.[12] While no clear statement about safety can be made on the basis of the current data, which were obtained from only 120 patients, there are data to show that in the absence of a prolonged tachycardia (≥120 bpm) the likelihood of complications is small.[12] The upper limit of 110 bpm for pulse rate, which was used in this study, seems to be safe.

Since the current study was not controlled by randomization, the question whether the favorable results can be attributed to home tocodynamometry needs to be addressed. Clearly factors such as daily telephone contacts, the availability of an open emergency line, and the posttransmission feedback may all have influenced perinatal outcome. Therefore, while the results for the matched nonmonitored high-risk group compare very favorably with those reported by others,[1-3] it is clear that firm conclusions about the potential role of home monitoring in improving perinatal outcome will need to be confirmed by studies in larger samples and other patient populations.

The current role of daily serum estriol monitoring in the insulin-dependent pregnant diabetic woman

Deborah A. Ray, M.D., John D. Yeast, M.D., and Roger K. Freeman, M.D.
Long Beach and Orange, California

This retrospective analysis of the use of serum estriol levels for antenatal assessment was performed in an effort to determine if routine, late third-trimester, daily serum estriol monitoring of insulin-dependent pregnant diabetic women can still be justified. Estriol profiles of 170 diabetic pregnancies, managed under a consistent protocol of weekly contraction stress tests and daily serum estriol assessments, were reviewed. A total of 4612 estriol determinations were performed. Nearly 4% of the estriol determinations showed a 35% fall from the mean of the previous three highest consecutive values. Forty-seven percent of the patients had at least one fall of this magnitude. Eighty-five percent of the fetal heart rate tests performed in association with an estriol fall were normal. A fall in estriol was not found to be associated with a higher risk of having a positive contraction stress test, either at the time the estriol fall was recognized or at any time during the patient's antepartum course. Although use of this strict protocol combining the use of weekly contraction stress tests and daily serum estriol determinations provided a safe method of antepartum assessment, there is little evidence to support the routine use of daily serum estriol monitoring in insulin-dependent pregnant diabetic women. (Am J Obstet Gynecol 1986;154:1257-63.)

Key words: Diabetes, estriol monitoring, antepartum assessment

Estriol production by the fetoplacental unit has been used as an index of fetal well-being for a number of years.[1] In the early 1960s, urinary estriol excretion was used to manage pregnancies complicated by diabetes mellitus.[2] Subsequently it became evident that frequent sampling was of great importance if estriol was to be of value as an indicator of fetal status in pregnancies complicated by diabetes. Also evidence was provided that normal estriol patterns indicate an absence of immediate fetal jeopardy.[3-5] Advances in radioimmunoassay techniques, in the mid-1970s, facilitated the routine determination of unconjugated or total plasma estriol levels in many clinical laboratories.[6-8] Clinical experience with both urinary estriol excretion and plasma estriol determinations was associated with improved perinatal outcome in pregnancies complicated by diabetes.[9-11] The need to perform unconjugated plasma estriol determinations on a daily basis with results available within 12 hours, in order to recognize a sudden fall in response to fetal distress with adequate time for successful intervention, was stressed. With the combination of fetal heart rate monitoring, amniotic fluid maturity studies, and daily estriol determinations, it was possible to reduce iatrogenic prematurity while decreasing the perinatal mortality resulting from stillbirths.[10]

Perinatal mortality in pregnancies complicated by diabetes has continued to decline.[12-14] This has been attributed to both better control of maternal diabetes and greater diligence in the use of antepartum fetal surveillance. Increasing importance has been placed on the use of biophysical techniques, including fetal heart rate monitoring and biophysical profile for the management of the pregnant diabetic woman.[13, 15] Estriol monitoring, because of the expense and degree of patient motivation required for its use, has been replaced by these biophysical techniques in many institutions. Because a high degree of success has been achieved in managing pregnancies complicated by diabetes in our institution, we have been reluctant to eliminate the use of estriol monitoring. Therefore we have undertaken this retrospective analysis in an effort to determine if the addition of routine, late third-trimester, daily serum estriol monitoring in insulin-dependent pregnant diabetic patients can still be justified in patients being managed with antepartum fetal heart rate testing.

Methods

Estriol profiles and complete clinical charts were reviewed for 170 insulin-dependent pregnant diabetic women who underwent antepartum fetal surveillance and subsequently were delivered at Women's Hospital, Memorial Hospital Medical Center, Long Beach, between January, 1979, and March, 1984. During this

period of time, antepartum assessment in pregnant diabetic patients entailed a consistent protocol of fetal heart rate stress testing and serum estriol levels. Insulin-dependent pregnant diabetic patients were begun on a regimen of weekly contraction stress tests (CSTs) at 34 weeks or earlier as the clinical situation warranted. Testing was begun as early as 26 weeks if intrauterine growth retardation, diabetic nephropathy, or hypertension was present. Antepartum fetal heart rate test interpretation was done by previously described criteria.[16] Biweekly serum estriol determinations were begun at 32 weeks and daily serum estriol measurements were begun at the thirty-fourth week or at the initiation of heart rate testing. Serum unconjugated estriol determinations were performed daily by radioimmunoassay, with the New England Nuclear estriol radioimmunoassay kit.[7] The results were available the same day. A significant fall in estriol was defined as a fall of ≥35% from the mean of the previous three highest consecutive values.[5] A significant fall in estriol elicited the performance of a fetal heart rate test and/or an evaluation of fetal lung maturity with subsequent consideration for delivery. A nonreactive, positive CST usually prompted immediate delivery. Patients with reactive, positive CSTs were delivered if the fetus was mature but were managed with daily estriol measurements and nonstress tests if the fetus was not mature. Equivocal CSTs, defined as suspicious or showing evidence of hyperstimulation, were repeated in 24 hours. Repetitively equivocal CSTs were followed by biweekly nonstress tests and consideration for delivery as soon as maturity could be assured. Patients were not delivered in the absence of documented fetal maturity unless (1) the antepartum fetal heart rate test was nonreactive and positive, (2) the antepartum fetal heart rate test was reactive, positive with abnormal estriol results, or (3) deteriorating maternal condition indicated prompt delivery.

The data for this analysis were taken from chart review and from a prospectively coded, computerized perinatal data base, which included all patients who underwent antepartum fetal heart rate testing and were delivered at Women's Hospital.

Results

There were a total of 4612 estriol determinations performed in the 170 insulin-dependent pregnant diabetic patients, an average of 27 per patient. One hundred seventy-one (3.7%) of the total estriol determinations showed significant falls, which occurred in 79 of the 170 patients (46.5%). A comparison of the 79 patients with at least one estriol fall with the 91 patients with no significant falls revealed no statistical difference with respect to age, parity, class of diabetes, incidence of hypertensive disease, or fetal distress in labor (Table I). Interestingly, although those patients with at least one significant fall in estriol did have more antepartum fetal heart rate tests per patient, there were no more positive CST results in that group than in those patients with no significant estriol falls. There were also no statistical differences in perinatal outcome (gestational age at delivery, indication for intervention, low Apgar scores, mean birth weight, stillbirth, neonatal death, or neonatal complications, Table I)

There was one intrauterine fetal death in this group.

APFHRT, Antepartum fetal heart rate test; ND, not done; NST, nonstress test.

This occurred in a patient at 39 weeks' gestation who refused elective intervention at 38 weeks. A reactive, negative CST was recorded 4 days before the antepartum death, and estriol values were normal until 1 day beforehand when the patient failed to return for daily estriol assessment. There were three neonatal deaths. One occurred in an infant delivered at 34 weeks' gestation without fetal lung maturity testing, after a nonreactive, positive CST, performed for decreased fetal movement, and a 54% fall in estriol level. The autopsy revealed respiratory distress syndrome, renal vein thrombosis, coagulopathy, and intraventricular bleeding. A second neonatal death was attributed to β-streptococcal sepsis, occurring in an infant delivered at 35 weeks with a lecithin/sphingomyelin ratio of 2.1/1. A third neonate, delivered electively at 39 weeks, died on the first day of life and was noted to have bilateral diaphragmatic hernias. Overall, the perinatal mortality rate was 23/1000.

A detailed analysis of the 171 estriol determinations showing a significant fall revealed that for 130 (76%) an antepartum fetal heart rate test was performed on the same day of or the day following the fall in estriol. One hundred ten (84.6%) of these antepartum tests were normal, with 18 (13.8%) being equivocal CSTs and two (1.5%) being positive CSTs.

In 28 falls in estriol (16.4%) the follow-up antepartum fetal heart rate test was performed 2 to 7 days after the significant fall. Twenty-two of these antepartum tests were noted to be normal, while six were equivocal CSTs. There were no positive CSTs noted in this group. The reasons for the delay in performing the test included an inability to contact the patient, patient noncompliance in returning for the tests, and delayed recognition of the estriol fall. An abnormal test, performed after a delay, prompted delivery in only one instance. This occurred in a Class F diabetic patient at 38 weeks, in whom a suspicious CST performed 5 days after a fall in estriol prompted an evaluation of fetal lung maturity and subsequent delivery. The estriol values in the interim were normal. No stillbirths or otherwise adverse outcomes were noted in this group of patients in whom performance of the antepartum test was delayed.

No antepartum fetal heart rate test was performed before delivery in 13 cases (7.6%). These patients were delivered without testing for the following reasons: The estriol fall led to an evaluation of fetal lung maturity and subsequent intervention (n = 5); previously scheduled elective induction of labor or cesarean section was performed (n = 2 each); spontaneous labor ensued (n = 3); or the estriol fall was unrecognized (n = 1).

Fourteen patients (8.3%) had falling estriol values as an indication for intervention (Table II). Only two patients had associated positive CSTs, and another six patients had associated equivocal CSTs. In only one of these patients with abnormal tests was the test performed before scheduled testing because of the finding of an estriol fall. Patients being tested at intervals of <7 days had additional indications or maternal risk factors necessitating more frequent testing. There was

no demonstrable morbidity associated with intervention secondary to an estriol fall.

A review of all antepartum fetal heart rate tests performed revealed 11 patients who had 13 positive CSTs. These tests were evenly distributed between the 79 patients with at least one fall in estriol and the 91 patients with no estriol falls. Of patients with at least one fall in estriol, 6.3% had a positive CST, compared with 6.6% of patients with no estriol falls. Gestational age at the time of the positive test ranged between 29 and 36 weeks (Table III). Estriol values were normal at the time of 10 positive CSTs in nine patients (Fig. 1). Intervention was delayed in six instances of positive CSTs because of normal estriol values. These six positive CSTs were reactive. The infants were subsequently delivered at 34 to 39 weeks, and all had benign neonatal courses.

A review of all the estriol profiles included an assessment of the number of significant falls that were ≥40% compared with those that fell between 35% and 40% (Table IV). A fall in estriol ≥40% was associated with no more abnormal antepartum fetal heart rate tests than a fall between 35% and 40%. In addition, the only two positive CSTs associated with a fall in estriol were associated with a fall >40%. If 40% had been used to define a significant estriol fall, there would have been

a decrease in estriol falls of 37% and 28% fewer patients would have had an estriol fall, without a failure to detect those falls associated with positive CSTs.

Comment

The incidence of intervention in diabetic pregnancies is necessarily high in an effort to avoid stillbirth.[9, 12] Only 22% of these 170 insulin-dependent diabetic patients entered spontaneous labor. Intervention, however, does carry with it the risk of complications secondary to prematurity. Therefore the timing of intervention is extremely important and complex. It is evident that a number of factors come into play in deciding when to intervene in a diabetic pregnancy. Gestational age, fetal lung maturity, maternal condition, antepartum fetal heart rate test results, and estriol profiles were all important factors leading to intervention in this group of patients. In only rare instances was a single factor the sole indication for intervention. A significant fall in estriol was a factor in the decision to intervene in 8% of patients in this study group. An estriol fall was the sole indication for intervention in only a single instance. Only one estriol fall (0.6%) was the initial inciting event that triggered further evaluation and subsequent intervention. Although a number of factors proved to be important in the decision to intervene, this study did not confirm the importance of using more than one modality of antepartum fetal surveillance, as suggested in previous studies of pregnant diabetic women.[11-13]

Estriol determinations, in addition to being a factor leading to intervention, were also used to prevent unnecessary premature intervention. Six patients (3.5%) between 31 and 36 weeks' gestation were allowed to continue the pregnancy despite reactive positive CSTs in the face of normal estriol profiles. Further assurance that these pregnancies did not require intervention was provided by the presence of reactivity on each of the positive CSTs. Daily nonstress tests evaluating reactivity may well have allowed a similar delay of intervention.

Estriol monitoring in pregnant diabetic patients requires daily testing with prompt evaluation of patients having significant falls.[5, 10] The antepartum fetal heart rate tests performed in association with estriol falls were normal 85% of the time. Only 1.5% of antepartum fetal heart rate tests performed at the time of a fall in estriol were positive CSTs. The incidence of positive CSTs among antepartum fetal heart rate tests performed in the absence of an estriol fall was 0.85%. This difference was not statistically different. The incidence of positive CSTs and the percent of patients having positive CSTs were not different when patients with at least one estriol fall were compared with patients with no estriol falls. Thus a fall in estriol was not associated with a higher risk of having a positive CST, either at the time the fall was recognized or at any time during the patient's antepartum course.

Table IV. Comparison of percent fall in estriol with incidence of abnormal antepartum fetal heart rate test

% Fall	*No. of estriol determinations*	*% Patients with at least 1 fall*	*% Associated with abnormal APFHRT*
≥40	107 (2.3%)	33.1	14.0*
35-40	64		17.2
≥35	171 (3.6%)	46.5	15.2

Numbers in parentheses are percentages of total estriol determinations performed; APFHRT, antepartum fetal heart rate test.

*The only two positive CSTs associated with a fall in estriol had a fall >40%.

It has been unclear what level of sensitivity is necessary to detect fetal jeopardy at all times and minimize the number of falsely positive values associated with the use of estriol monitoring. Because of the relatively low incidence of positive CSTs in a well-controlled diabetic population, it has been difficult to establish what percent fall in estriol should elicit further evaluation. The data from this study, as well as others, suggest that a 40% fall from the mean of the previous three highest consecutive values is adequately sensitive.[11, 12] The use of a 40% fall limit in this study group would have decreased the number of abnormal estriol values by 37% and decreased the number of patients with at least one significant fall by 28%, without failing to detect those patients with positive CSTs.

In conclusion, the current role of daily serum estriol determinations in the management of the insulin-dependent pregnant diabetic patient can be summarized as follows:

1. Estriol results may provide information to help determine timing of intervention; however, rarely if ever will estriol results alone prompt intervention or initiate evaluation that leads to intervention.

2. Daily estriol results showing normal values may allow delay of intervention in patients <37 weeks' gestation with positive CSTs; however, daily nonstress tests evaluating reactivity may provide the same assurance that intervention can be delayed.

3. Routine daily estriol screening is expensive and time-consuming for the patient and adds little or nothing to the detection of fetal jeopardy when used in conjunction with fetal heart rate stress testing.

4. If daily estriol monitoring is to be used in certain circumstances, a 40% fall limit is an adequately sensitive cutoff for further evaluation.

Although this strict protocol combining the use of weekly CSTs and daily serum estriol determinations

provided a safe method of antepartum assessment, we cannot justify the continued routine use of daily serum estriol monitoring in insulin-dependent pregnant diabetic patients. Other methods of fetal surveillance that are less time-consuming and cumbersome, such as midweek nonstress tests or fetal movement counting, may prove to be effective adjuncts to weekly CSTs in pregnancies complicated by insulin-dependent diabetes. Investigation in these areas is currently in progress.

Discussion

DR. ROBERT RESNIK, San Diego, California. Dr. Freeman and his colleagues have reported the pregnancy outcomes of 170 gravid women with type I diabetes mellitus, with respect to the comparative reliability and sensitivity of antepartum fetal heart rate monitoring and daily serum estriol testing. It has been the policy at their institution for several years to use these dual techniques to evaluate fetal well-being in the diabetic patient.

Data from this type of retrospective study can be difficult to interpret. This is due to the fact that management protocols that are not prospective in nature allow more for clinical flexibility than for critical scientific investigation.

Nonetheless, it seems clear from Dr. Freeman's data that antepartum fetal heart rate monitoring is a satisfactory technique for monitoring fetal well-being and that serum estriol testing, and I quote from the text, "adds little or nothing to detection of fetal jeopardy when used in conjunction with fetal heart rate testing."

This is not surprising when one considers some of the biochemical aspects of estriol synthesis. The rationale for its use in monitoring high-risk pregnancies is based on the production of enormous amounts of estrogenic precursors by the fetal adrenal gland, which are then converted to C-18 steroids by the placenta. The placental mass apparently has a large reserve in enzymatic capability for aromatization of ring A or the final conversion of 16α-hydroxylated DHEA to estriol. Consequently, only sharp decreases in fetal precursor production or profound placental dysfunction will result in decreased total estriol production. The clinical significance of these biochemical realities is that a fetus or its placenta must be in serious jeopardy before the clinical status will be reflected by a fall in maternal serum estriol.

Despite the lack of well-controlled clinical studies in the past, a serum estriol value in the normal range or increasing values have generally been reassuring to clinicians. However, a decreasing estriol value has been misleading with respect to fetal status more often than not. This is borne out by the finding in this study that 46% of the patient population had at least one significant drop in estriol and there was only one fetal death in the entire group. Furthermore, in only one instance was a fall in estriol the primary event that ultimately triggered obstetric intervention.

This study confirms the very limited value of estriol in monitoring the diabetic pregnancy and reinforces the use of antepartum fetal heart rate monitoring for high-risk pregnancies in general. I would ask Dr. Freeman the following question: At the outset of the study, it is stated that estriol levels would not be used in decision making regarding delivery timing unless the CST was interpreted as being positive but reactive, and the fetal lung was immature. If so, how many of the 170 patients met those specific criteria, and if the number

is small, as I would expect it would be, can you justify the expense of an estriol laboratory?

Dr. James Caillouette, Pasadena, California. I would like to add one more nail to the estriol coffin. I thank Dr. Freeman for providing me the opportunity to do so.

In 1970, I was the formal discussant for Dr. Roger Hoag's paper on the use of estriol testing for the evaluation of fetal well-being. I was skeptical at that time and registered significant reservations.

During the past 15 years many articles have been written on the subject of estriol testing for evaluation of fetal well-being. Most present either mixed or negative data.

Both Dr. Freeman and Dr. Resnik have made clear that this test should at long last be given a decent burial.

Dr. Freeman (Closing). Dr. Resnik, it is ironic that you were one of the first to point out your skepticism about the value of estriol monitoring for fetal well-being and now you are discussing this article. You now have some data to support your bias and I want to compliment you on your previous clairvoyance.

Results of microsurgical treatment of tubal infertility and early second-look laparoscopy in the post–pelvic inflammatory disease patient: Implications for in vitro fertilization

Karl Luber, M.D., Charles C. Beeson, M.D., Joseph F. Kennedy, M.D., Benito Villanueva, M.D., and Philip E. Young, M.D.

San Diego, California

Sixty-nine patients with tubal infertility secondary to pelvic inflammatory disease were surgically treated by one of three infertility surgeons, who used microsurgery for repair of the tubal pathologic condition and early second-look laparoscopy 6 to 30 days postoperatively for lysis of postoperative adhesions. No patient was included in this group whose disease was thought to have originated from endometriosis or prior abdominal surgery. The average follow-up time was 43.1 months (range 12 to 85.9). Nine patients were excluded from the analysis. Pregnancy outcome by procedure, expressed as the percentage of patients conceiving, was as follows: adhesiolysis, 69% (61% term, 8% ectopic); fimbrioplasty, 35% (25% term, 10% ectopic); salpingostomy, 30% (18% term, 12% ectopic); and cornual implantation, 60% (40% term, 20% ectopic). No added therapeutic value could be attributed to the use of early second-look laparoscopy. Given the relatively poor outcome of fimbrioplasty and salpingostomy, it may be prudent to advise patients with bilateral partial and/or total tubal occlusion against tuboplasty in favor of in vitro fertilization and embryo transfer. (AM J OBSTET GYNECOL 1986;154:1264-70.)

Key words: Tubal infertility, microsurgical treatment, laparoscopy, second look, inflammatory disease, in vitro fertilization

Approximately 13% of women who experience a single episode of pelvic inflammatory disease will suffer infertility secondary to postinfectious tubal occlusive disease.[1] In the United States during the late 1970s, 10 to 13 cases of pelvic inflammatory disease per thousand women aged 13 to 34 years were reported annually.[2] Westrom[3] calculates that this incidence corresponds to approximately 500,000 new cases of postinfectious tubal infertility per year. Often these women are nulliparous and are unaware of having had an episode of pelvic inflammatory disease.[4] Tubal corrective surgery has been the main approach to the treatment of this cause of infertility.[5] Microsurgical technique has been shown to improve the results of such surgery in some studies[5-8] but not in others.[9, 10] This article (1) examines the results of tubal microsurgery for infertility when the surgery is followed by early second-look laparoscopy 6 to 30 days postoperatively to lyse postoperative adhesions in patients suffering from postinflammatory tubal adhesive disease and (2) considers the implications of these results in deciding in the future which patients with tubal-factor infertility would be best served by microsurgery and which by in vitro fertilization and embryo transfer.

Material and methods

Study group. The study group originally consisted of 69 women who came to a private fertility clinic with a chief complaint of infertility (defined as a failure to conceive after 1 year of adequate exposure), whose infertility was determined, after study, to be due to postinflammatory tubal disease, and who underwent microsurgery and early second-look laparoscopy between April, 1978, and June, 1983. The average age of the patients at the time of surgery was 28.3 years (range 22.5 to 39.5). The patients came from a broad spectrum of socioeconomic and racial backgrounds. Of the 69 patients, three had undergone previous surgery for the correction of infertility. Nine patients were excluded from the analysis for the following reasons: four had less than 1 year of follow-up; four had less than 1 year of sexual exposure after the surgery; and one was found to have one normal tube at the time of surgery that required no correction. Thus the final group available for analysis consisted of 60 patients.

Evaluation. All patients in this group underwent an infertility evaluation prior to surgery, which included basal body temperature charts, postcoital test, semen analysis of the male partner, demonstration of ovulation (usually with a midluteal serum progesterone de-

termination), hysterosalpingography, and preoperative laparascopy with chromopertubation.

Procedures. The operative procedures were performed by one of the three infertility surgeons participating in this study at one of three hospitals in the San Diego area. The three surgeons are partners in private practice, regularly assist each other during surgery, and have thus evolved a common technique. Most of the surgeries were performed at University of California, San Diego, Medical Center. Reconstruction of the fallopian tubes and lysis of pelvic adhesions were performed with the use of microsurgical techniques, including minimal tissue trauma, meticulous hemostasis by means of fine electrocautery, reperitonealization of all denuded surfaces, prevention of tissue desiccation with continuous irrigation, and 10× to 16× magnification with an operating microscope. Vicryl suture (8-0) was used on the fallopian tubes. All patients received antibiotics and steroids before, during, and after operation. Thirteen patients underwent temporary suspension of the ovaries to the round ligament or uterine fundus with a 1-0 Prolene suture in addition to their primary tubal procedure. These suspensions were removed at the time of second-look laparoscopy. Immediately before the incision was closed, 200 ml of Hyskon or, in some early cases, 500 ml of 32% dextran 70 was instilled into the peritoneal cavity.

Early second-look laparoscopy was performed on all but one patient between 6 and 30 days postoperatively, the mean interval being 11.1 days. At the time of early second-look laparoscopy, the surgical outcome was evaluated for tubal patency and extent of adhesions. Usually the adhesions found at early second-look laparoscopy were able to be cleared by means of a blunt probe inserted suprapubicly. Ovarian suspensions, when present, were released, and phimotic tubal ostia were opened when necessary. On conclusion of the procedure, 200 ml of Hyskon or 500 ml of 32% dextran 70 was instilled in the peritoneal cavity through the laparoscopic trocar sleeve.

Classification of cases. Cases were classified as adhesiolysis, fimbrioplasty, salpingostomy, or cornual resection. As recommended by the International Fertility Society,[5] fimbrioplasty was separated from salpingostomy by the preoperative presence of a tubal lumen. When a patient required a different procedure on each adnexum, the patient was classified according to the adnexum of lesser pathology. This classification

method was used (1) because it is assumed that if these patients become pregnant, it will be by way of the less affected tube and (2) because the classification is in keeping with the recommendatons for standardization put forth by other authors.[5, 9] Patients who required cornual resection of either tube, with or without additional surgery, were separately analyzed.

It is evident that since the patient's disease state at the time of exploratory laparotomy dictates the type of surgery performed, classification of patients by type of surgery performed is also a classification of the extent of disease.

Results

The outcome of these procedures is summarized in Table I. Intrauterine pregnancy rates are broken down into term pregnancy rates and spontaneous abortion rates. Ectopic gestations are listed separately. In addition, we have included the category of "eventual intrauterine pregnancy rate," which includes patients who eventually had an intrauterine pregnancy but only after a postoperative ectopic pregnancy, and the category of "eventual term pregnancy rate," which includes patients who eventually delivered a viable fetus but only after a postoperative abortion or an ectopic pregnancy.

For the 60 patients included in our analysis, the average follow-up time was 43.1 months (range 12 to 85.9). The intrauterine pregnancy rate varied inversely, and the ectopic rate varied directly, according to the extent of disease encountered and the complexity of the procedure required. Adhesiolysis resulted in the highest term delivery rate (62%) and the lowest incidence of ectopic gestations (8%). Salpingostomy produced the lowest term delivery rate (18%) and the highest ectopic rate (12%). Fimbrioplasty resulted in intermediate values of term delivery (25%) and ectopic gestation (10%). The differences were statistically significant for adhesiolysis versus both fimbrioplasty and salpingostomy (Table I). Any conclusions regarding the cornual resection group are limited by its size, especially since within this small group there are three subsets (two patients had cornual reanastomoses after resection, two patients had "mixed" procedures [cornual resections combined with distal tubal surgery], and six patients had cornual reimplantation after resection). Nevertheless, a high rate of both term gestations (40%) and ectopic gestations (20%) was noted within this entire group, and the intrauterine pregnancy rate for this

group, versus the salpingostomy rate, was statistically significant (Table I).

The percentages of patients who achieved two or more pregnancies postoperatively were as follows: adhesiolysis, 32%; fimbrioplasty, 5%; salpingostomy, 12%; and cornual resection, 20%. Since many of our patients chose to have only one pregnancy after surgery, these data do not represent the total capacity for multiparity after surgery.

There was no statistically significant difference in the time interval from procedure to conception among the four surgical groups. The shortest average time was 10.9 months (fimbrioplasty), and the longest was 15.3 months (adhesiolysis). The average time interval from procedure to term pregnancy for the entire group of 60 patients was 13.7 months, whereas the average time interval from procedure to ectopic pregnancy was 9.1 months.

When the pregnant and nonpregnant groups were analyzed, no statistically significant differences were found regarding the ages of the patients (28 versus 28.7 years), a history of previous corrective or abdominal surgery, the time from operation to early second-look laparoscopy, or the follow-up time. Ovarian suspension was generally performed for the most severe adhesive states. Thirteen patients underwent ovarian suspension as part of their procedures, but distribution of this surgical modification among the four procedures occurred in such a way that no conclusion could be drawn as to its efficacy. There were six ovarian suspensions in the pregnant group and seven in the nonpregnant group.

The time interval from operation to early second-look laparoscopy did not statistically differ for the pregnant versus the nonpregnant groups, for the ectopic versus the term groups, or for each of the four procedure groups.

At early second-look laparoscopy, adhesions were graded on a scale from 0 to 3 where 0 equaled no adhesion, 1 equaled filmy adhesions, 2 equaled moderate adhesions, and 3 equaled dense, difficult-to-manage adhesions. When patients were placed into two groups having grade 0 to grade 1 adhesions in one group and grade 2 to grade 3 adhesions in the other group, there was no statistically significant difference demonstrable in the probability of having either an ectopic or a term gestation, in the probability of becoming pregnant, or, for those patients in the pregnant group, in the time interval between operation and conception.

Comment

It has been repeatedly demonstrated[9, 11-14] that the intrauterine pregnancy outcome after tubal surgery is inversely proportional, and the ectopic pregnancy outcome directly proportional, to the extent of the patient's original disease. This finding has become virtually an axiom in tubal surgery. Our data confirm these observations. Tables II to IV suggest that, in the literature, this relationship holds true whether conventional or microsurgical techniques are used and whether or not early second-look laparoscopy is added to the operative procedure. These tables incidentally also tend to support the view, with which we concur, that there is no clear-cut advantage to microsurgery with or without early second-look laparoscopy over conventional surgery for the treatment of any of the disease categories.

The inverse relationship described above between degree of tubal disease and pregnancy outcome after surgical correction of tubal infertility does not pertain to in vitro fertilization with embryo transfer, in which the intrauterine pregnancy outcome is independent of the degree of tubal pathology,[16] provided that the ovaries are accessible for oocyte retrieval. On the basis of this important difference between surgery and in vitro fertilization with embryo transfer, Wood and Trounson[16] have suggested that "in vitro fertilization and embryo transfer may be preferred to tubal surgery where [the expected success rate of the surgery is] less than the cumulative pregnancy rate of three laparoscopies for [in vitro fertilization] (about 40%)."

Table V shows that data for our community hospital–based in vitro fertilization with embryo transfer

program for the calendar year 1985 to August 30, 1985. Probably the most useful way of reporting in vitro fertilization with embryo transfer pregnancy outcomes, from the patient's point of view, is the pregnancy rate per laparoscopy. In our hands over this period, one in vitro fertilization with embryo transfer laparoscopy had an intrauterine pregnancy rate of 21% and an ectopic rate of 0%, regardless of the extent of tubal pathology. These data are similar to those reported by others[16] and, as reported in this paper, compare with postsurgical intrauterine pregnancy rates of 61%, 25%, and 18% following adhesiolysis, fimbrioplasty, and salpingostomy, respectively, and with corresponding ectopic rates of 8%, 10%, and 12%. It is important to realize that this comparison is between patient groups handled by the same three physicians for each group and therefore represents truly comparable results.

By way of further comparison, one complete in vitro fertilization with embryo transfer cycle costs less than half as much as a complete microsurgery–early second-look laparoscopy cycle and results in dramatically less discomfort, risk, and postoperative disability. It has the additional advantage that the pregnancy outcome is known 30 days after the cycle has begun, whereas the waiting time for pregnancy after surgery may be up to 4 years.

These considerations suggest to us that, in our hands, most cases of tubal infertility amenable to adhesiolysis would be best treated with the surgical approach. However, in those cases in which it is believed preoperatively, on the basis of hysterosalpingography and/or laparoscopy, that fimbrioplasty or salpingostomy would be required in the surgical treatment of the tubal pathology, in vitro fertilization will in most cases be the preferred modality of treatment. This conclusion is in agreement with the conclusions reached by others.[13, 16]

We conclude that microadhesiolysis with early second-look laparoscopy is a highly successful surgical procedure (61% intrauterine pregnancy rate) but that microfimbrioplasty with early second-look laparoscopy (25% intrauterine pregnancy rate) and microsalpingostomy with early second-look laparoscopy (18% intrauterine pregnancy rate) are much less so. In our hands, patients requiring either of these latter two procedures appear in most cases to be better advised to attempt in vitro fertilization with embryo transfer (21% intrauterine pregnancy rate per laparoscopy event), since even a single in vitro fertilization laparoscopy has an intrauterine pregnancy rate similar to that of microfimbrioplasty and/or microsalpingostomy but is associated with less discomfort, disability, risk of ectopic pregnancy, and expense for the patient.

Discussion

Dr. Richard M. Soderstrom, Seattle, Washington. With the increase of pelvic inflammatory disease and the marked decrease in babies available for adoption, it's no wonder that microsurgery has received such ferocious attention from reproductive surgeons. Despite many sophisticated improvements in microsurgical techniques and instruments, viable pregnancy in most circumstances follows such surgery in less than half the patients subjected to this major surgical event. Follow-up laparoscopy has been recommended by most surgeons; some recommend it within a few weeks of microsurgery, whereas others recommend a 4- to 6-month delay. In this flurry of infertility surgery, the patients and their physicians have watched with interest the glamour and advancements of in vitro fertilization and embyro transfer. Although the chemical pregnancy rate in most seasoned centers is impressive, the number of live births has been disappointing Nevertheless, improvement is reported with each year.

Dr. Young and his associates have analyzed 60 patients who had damaged fallopian tubes following one or more attacks of pelvic inflammatory disease and have searched their experience for success and failure. They

have considered ectopic pregnancy as a failure, and I'm sure their patients agree. They have separated this group of 60 patients into four categories according to procedure, hoping to answer two questions that I interpret as being the following. First, when should the surgeons recommend in vitro fertilization? Second, should they recommend microsurgery instead? In doing so, Dr. Young and associates were unable to demonstrate a startling improvement following early second-look laparoscopy when their results were compared with those reported in the current literature.

However, this study does not compare *late* second-look laparoscopy and the resultant pregnancy rate, which is still favored by many surgeons. Perhaps the lysis of freshly formed adhesions promotes re-formation of the same adhesions. Personally, I've been impressed with the paucity of adhesion re-formation after laparoscopic lysis of old adhesions has been performed for other indications.

Unfortunately the confidence limits are too broad, and thus the power of this study is too weak to answer those two questions. With such a small series sprinkled with confounding variables, such as the extent of adhesions in each subgroup, a remarkable difference in outcome would have to be evident before any cause-and-effect relationship could be entertained. Diseased tubes do not heal well under the best conditions or at the hands of the best surgeon. To classify the extent of the adhesions is helpful, but the other variables, such as epithelial integrity of the tube, will soften the analysis.

All of the patients received preoperative laparoscopy, and in the article there is a quote from the literature regarding adhesiolysis in three different modes: (1) the conventional technique, in which live-birth rates ranged from 48% down to 32%, (2) microsurgical techniques, in which rates were as low as 25% and as high as 62%, and (3) creative laparoscopy, as reported by Gomel, who had 92 cases with a live-birth rate of 58.7%. In Gomel's series, however, all the adhesions were handled by operative laparoscopy, not by microsurgery, and I wish to ask Dr. Young whether any of the patients in his practice underwent laparoscopic lysis of adhesions, rather than microsurgery, or did all of them come to microsurgery? I believe that if the latter was the case, this would certainly influence the statistics.

I was somewhat startled by the cost comparison of an in vitro fertilization in San Diego versus microsurgery. This is not the case in Seattle, since microsurgery is only about 20% higher than one course of laparoscopy for vitro fertilization.

Although the inverse relationship between pregnancy outcome and the degree of tubal disease does not pertain to in vitro fertilization, one cannot assume that all those patients who would have conceived after microsurgery will conceive after in vitro fertilization. Let us assume that the statistics from abroad and from Australia give a 20% expected live-birth rate following one laparoscopy. Dr. Young implies in his presentation that these statistics would hold up with subsequent laparoscopies, at least after four laparoscopies with in vitro fertilization. It would mean that after one laparoscopy in 100 patients, there would be 20 live births. After two laparoscopies, there would be 16 more; after three there would be 13 more; and after four there would be 10 more. He therefore predicts 59 pregnancies in 100 patients who would elect four laparoscopic retrievals for in vitro fertilization procedures—an ambitious statistic that has yet to be proved. If the 20 patients who would have become pregnant following fimbrioplasty or salpingostomy had instead chosen in vitro fertilization and embryo transfer, the same statistics would apply. Thus eight of those 20 patients would not conceive.

We are all here today because we are certain of our impressions but frequently skeptical of facts. Dr. Young and his associates have reminded all of us, with this analysis, that the benefit-risk ratio of microsurgery for infertility must receive periodic reappraisal and be compared with the ratio for newer physiologic and technologic advances in the area of reproductive health.

Dr. Kelvin Churches, Carlton, Australia. I'm hesitant to speak, because I have no firm figures from the in vitro fertilization units, but I think that when you talk about the leading in vitro fertilization units in Australia, both come from Melbourne, one at my hospital, the Royal Women's Hospital, and one at Queen Victoria Hospital. I must be less optimistic than Dr. Young about the projections, and I agree with Dr. Soderstrom in that, to the best of my knowledge of the patients in the in vitro fertilization programs, each of which have up to three laparoscopies, the current yearly rate of successful pregnancy varies from 12% to 20%, and it hasn't gone above 20%.

Dr. Simon Henderson, Los Angeles, California. Thank you, Dr. Young, for that good presentation. However, I endorse what Dr. Soderstrom said, namely, that there is no real proof that early laparoscopy is better than late laparoscopy or than laparoscopy done only if the patient doesn't get pregnant. In addition, I strongly suggest caution about term pregnancy results with in vitro fertilization. In fact, I think all of us who have read the article in *Fertility and Sterility* by Dr. Soules—the title of which is "IVF results: Let's be honest"—will be aware of the somewhat flamboyant pregnancy rates reported in the press. I think that caution is therefore appropriate. I also agree with Dr. Churches' comments that probably, even in the best clinics, we're not getting much more than a 20%, and maybe in some months a 30%, ongoing pregnancy rate with in vitro fertilization.

I also wish to comment on the number of microsurgical cases you are doing. By my calculations the rate is probably about one procedure a month over the 6 years, coming up with your total of 69 cases. In my practice, I find that microsurgical operations for patients with pelvic inflammatory disease represent about half of my microsurgery; 25% are reversals of sterilization, and the last 25% are for endometriosis. Thus I estimate that you probably do two microsurgical tubal procedures a month. I forget how many partners you said you have, but I think it was two or three, which

means only a few microsurgical cases a month for each of you. Most microsurgeons believe that they should be doing about two or three cases a week to be keeping their hand in, so to speak. In addition, your results with the salpingostomies for the hydrosalpinx, the very bad cases, were a bit low, that is, 18%. These results are low in comparison with Winston's and Gomel's results (25% to 35% term pregnancy rates), which are similar to what I find in my office, and may reflect the relatively few microsurgical procedures you are doing.

Dr. Donald Minkler, San Francisco, California. Dr. Young, your presentation has raised some valuable and interesting questions that might have applicability in other parts of the world. I have had an opportunity to observe very high levels of infertility in developing countries, particularly in Africa, because of the tubal factor caused by untreated sexually transmitted disease. In most institutions in these areas, surgical treatment is simply not feasible because it's too costly and because the demands on very limited resources for surgery are too high to allow for elective procedures such as tuboplasty. At the same time the social consequences of infertility for the woman are very profound. Therefore, I want to ask whether you think that the cost factor and the level of laboratory sophistication that is required for in vitro fertilization have reached, or will soon reach, a point where it is realistic for us to begin to think about this procedure as a practical alternative to surgical management in less developed countries.

Dr. Young (Closing). With respect to the point that Dr. Soderstrom brought up, there's no question that I agree with him a hundred percent that many things affect the outcome. It's been proved repeatedly, by multiple authors, that such factors as the degree of density of adhesions, the number of adhesions, and the integrity of the epitheal lining, besides the hydrosalpinx, all affect the outcome.

With respect to whether we have any laparoscopic lysis patients, we have a few who were not included in this study, but they are very few. Basically I have not been comfortable over the years with any heroic laparoscopic lysis of adhesions. If there are a few little adhesions, I think it's a great operation, but as the procedure begins to get trickier and I wonder where the ureter is and all that, I become "chicken." Thus most of our laparoscopic lysis cases have, in fact, been open cases.

Dr. Churches' comment is correct. All the major in vitro fertilization groups are reporting, except for England, where they keep pushing 30%, maximum pregnancy rates per laparoscopy of 15% to 20%, which I'm sure is no different statistically from these numbers that I'm showing you here. I suspect that at this point in time, you can reasonably look at in vitro fertilization as a 15% to 20% proposition and can make your calculations based on that.

In regard to Dr. Henderson's comments, the cases discussed herein represent only those cases in which disease was believed, after workup, to have resulted from infection. Our total microsurgery caseload for the study period, including sterilization reversals and other problems, was in excess of 200 cases, which I believe is more than enough to "keep our hands in." In any case, however, we do a modest number of these procedures, and the results as we show them are the results that we get.

The important point of this article, from my point of view, was to emphasize the applicability of both in vitro fertilization and microsurgery to the clinical private practice of infertility and to begin the process that we must all now go through, of deciding where the new in vitro fertilization technology fits into our more conventional treatment patterns. In vitro fertilization is no longer a "last ditch" or experimental tool. In answer to the last question, as to whether in vitro fertilization is applicable in less developed countries, the procedure is highly sophisticated and requires laboratory and physician support that, at least in the immediate future, I can only imagine being possible in highly sophisticated countries. I don't see it as something that's going to be imported to New Guinea, for example, in the near future.

Fetomaternal hemorrhage associated with umbilical vein thrombosis

Case report

Roger W. Hoag, M.D.
Berkeley and San Francisco, California

Antenatal thrombosis of the umbilical vein is usually a fatal condition for the fetus or neonate. The probable pathophysiology of this condition and its relationship to fetomaternal hemorrhage is discussed. A systematic study of the entire umbilical cord should be done when fetomaternal bleeding is diagnosed. (Am J Obstet Gynecol 1986;154:1271-4.)

Key words: Fetomaternal hemorrhage, umbilical vein thrombosis

Massive fetomaternal hemorrhage as the cause of perinatal mortality and morbidity occurs in approximately 1:800 deliveries and accounts for 3% of perinatal mortality. Massive fetomaternal hemorrhage has been defined as bleeding in which greater than 150 ml of fetal blood is found in the maternal circulation. Fetomaternal hemorrhage was found to be a cause of fetal death occurring before labor in 4 of 29 cases in which no other cause could be assigned.[1] Therefore a Betke-Kleihauer test should be done when an unexplained fetal death in utero or nonhemolytic anemia is found in the neonate. Thrombosis of the umbilical vein has been a condition only rarely recognized, with only 20 cases reported in the literature up to 1967. More cases have been added in the recent literature[2-5]; however, no report was found in which umbilical vein thrombosis and fetomaternal hemorrhage have been associated.

Case report

On a Sunday afternoon a 32-year-old woman, gravida 3, para 2, at 38 weeks' gestation in a totally uneventful pregnancy, reported having decreased fetal movement since that morning. A nonstress test was planned for the following morning. Twelve hours later a call revealed that she was still anxious about the relative lack of fetal movement, and she was admitted for observation. She had had no contractions, abdominal pain, or vaginal bleeding. She reported rust-colored urine without urinary urgency, frequency, or dysuria. Her past history was unremarkable, and her past obstetric history was that of two term spontaneous vaginal deliveries of two normal infants.

On the patient's admission to the hospital at 0100 hours (Monday), the fetal heart was observed to be steady at 150 bpm. The patient was having no contractions or vaginal bleeding, and the cervix was closed. The uterus was nontender on palpation. Blood pressure, pulse, and temperature were within normal limits. Observation of a voided admission urine specimen was cloudy yellow with no albumin present. A nonstress test was carried out; no accelerations were seen with two fetal movements observed by the nurse and the patient, and test results were reported as nonreactive. Nipple stimulation (contraction stress test) promptly induced uterine contractions, and the fetal heart exhibited many variable and some late decelerations. The nipple stimulation was halted, and the contractions gradually slowed to 6-minute intervals but lasted 70 to 80 seconds. Preparations were initiated for delivery by cesarean section. However, fetal bradycardia (90 bpm) developed and lasted several minutes, followed by a slow return to a baseline rate of 100 to 110 bpm but with loss of beat-to-beat variability. Review of the monitor records revealed the presence of a transient sinusoidal pattern in the nonstress test strip. Additional preparations were made for an emergency cesarean section; general anesthesia was induced, and 7 minutes later a pale, limp, 3.17 kg female infant with Apgar scores of 0 and 0 at 1 and 5 minutes was delivered. The amniotic fluid was meconium stained. There was no visible evidence of premature separation of the placenta, cord entanglements, forelying cord, compression, or hematomas. The umbilical cord appeared thin or empty. A cord blood sample was obtained with difficulty. Resuscitative efforts included intracardiac injection of epinephrine, which stimulated an irregular heart rate of 20 to 40 bpm to no avail, and the baby was pronounced dead

From the Department of Obstetrics and Gynecology, Alta Bates Hospital, Berkeley, and the University of California, San Francisco.
Presented at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.
Reprint requests: Roger W. Hoag, M.D., 2845 Garber St., Berkeley, CA 94705.

after 30 minutes. The central hematocrit was 16%. Blood from the umbilical vein catheter revealed severe acidosis with a pH value of 6.46, P_{CO_2} of 143.3, P_{O_2} of 14.5, and base excess of −32. The mother's admission hemoglobin was 12.7 gm/dl, and a Betke-Kleihauer test of blood drawn before delivery revealed a 5.1% fetal hemoglobin, with an estimated fetal blood volume in the maternal circulation of 185 ml. Normal fetal blood volume calculated at 75% of body weight would equal 240 ml. A catheterized urine specimen (maternal) was negative for protein and contained many red blood cells, and 10 to 20 white blood cells per high, dry field. Urine culture yielded no growth. Maternal plasma hemoglobin was 0.7%, with a normal range in our laboratory of 0 to 5 mg/dl. Direct Coombs' test showed negative results. The mother's blood was type O, Rh positive, as was the baby's.

The placenta was meconium stained and exhibited a 30 ml adherent clot near a margin. Deep to the clot were several large infarcts, one of which was 2.5 cm in diameter; most were old, but one was recent. The cord was sectioned every 2 cm. In one section of the cord the umbilical vein was found to contain a thrombus adherent to the wall of the vein and completely occluded the vein. Microscopically there were leukocytes, platelet aggregates, and fibrin lines of Zahn in the thrombus, which was thought to establish a premortem onset of the thrombotic process of greater than 24 hours. Postmortem examination revealed an infant with a waxy pallor consistent with exsanguination with collapsed vessels; otherwise, gross and microscopic findings were within normal limits. No thrombosis of the ductus venosis was found.

Comment

When the umbilical vein is totally occluded, blood from the fetal circulation of the placenta has no possibility of return to the fetus. As blood from the fetal arterial side continues to be pumped into the placenta, the fetomaternal pressure differential increases across the hemochoriol membrane. It is postulated that this factor may contribute to fetomaternal transfusion by producing leakage or may increase the pressure for leaks in areas of preexisting lesions or damage to endothelium and syncytial membrane at their junction with decidual tissue. However, umbilical vein thrombosis associated with fetal anemia and a failing circulation could be due to stasis of flow, which is a known factor in producing or adding to a thrombus. Otherwise, in the absence of compression, torsion, trauma, or hematoma, the thrombosis is unexplained. Even if the thrombosis resulted from stasis of circulation, it may still have contributed to the downward spiral of anemia, hypovolemia, distress, acidosis, and death.

Testing for fetomaternal hemorrhage should be done in every case of unexplained fetal death or nonhemolytic anemia in the newborn. It is additionally recommended that careful longitudinal opening of the umbilical vein or sectioning of the cord every 1 to 2 cm should also be done to search for thrombosis of the umbilical vein. This condition may, in fact, be present more often than was previously recognized.

Discussion

DR. JOHN J. MOLITOR, Fullerton California. Dr. Hoag has presented us with two fascinating mishaps of fetal circulation. One, umbilical vein thrombosis, is exceedingly rare, as he has pointed out. The other, fetomaternal hemorrhage, is more common than most of us realize and is even more commonly unrecognized. Many obstetricians are not familiar with massive fetomaternal hemorrhage. Usually the two events have been reported as occurring separately. In Dr. Hoag's case they were associated in the same patient. The extreme rarity of this association precludes a meaningful discussion based on statistics or reports of past experience because there simply are none. Dr. Hoag postulates that occlusion of the umbilical vein increases the pressure in the fetal vascular spaces of the placenta, predisposing or causing leakage of fetal blood into the maternal vascular compartment. This hypothesis certainly is attractive and seems plausible just on the basis of hydraulics. If it is operative, however, it is uncommon and leaves unexplained the cause of the much more common and often lethal massive fetomaternal hemorrhage. Today anything that causes fetal distress or intrauterine fetal death will command the attention of the obstetrician as never before. In addition to our scientific curiosity, another reason compels our attention. The reason, of course, is the difficult and distressing medicolegal climate in which we work. I first became interested in this problem when I had a case, approximately 5 years ago, that resulted in a brain-damaged baby and, of course, a lawsuit. Such an experience is guaranteed to stimulate your interest.

The Europeans have recognized and written about massive fetomaternal hemorrhage for years, but comparatively little has been written in the American literature. The reason is unclear, but I suspect it is that the focus has been on other, more common problems that also have a potentially greater economic impact, such as diabetes complicating pregnancy, uteroplacental insufficiency, intrauterine growth retardation, and pregnancy-induced hypertension. The last three of these problems might conceivably have a cause in com-

mon with each other and possibly with fetomaternal hemorrhage as well—as recent studies of placentation have indicated.

Paradoxically, the bleeding of the fetus into the mother holds the greatest clinical significance for the obstetrician at the two extremes of the magnitude of the bleeding. It has been known for years that fetal blood cells get into the maternal circulation. Weiner[1] first proposed, in 1948, that transplacental hemorrhage of fetal Rh-positive red blood cells into the circulation of the Rh-negative mother was the cause of Rh isoimmunization. This proposal was confirmed in 1954 by Chown,[2] who reported the delivery of a very anemic Rh-positive baby from an Rh-negative primipara. The mother was found to have 5% Rh-positive fetal red blood cells in her circulation, and she promptly developed an Rh antibody response. It has been shown subsequently that as little as 0.1 ml of fetal blood can cause an antibody response in the mother. Fetomaternal bleeding in the range of 30 to 40 ml can cause antibody response but usually does not seriously impair fetal hemodynamics. The massive fetomaternal hemorrhage, over 150 ml, can kill the fetus or seriously compromise its circulation.

The acid elution test developed by Kleihauer and associates in 1957 and now known as the Betke-Kleihauer test is a very accurate, sensitive method of differentiating fetal red cells from adult red cells and allows the quantitative evaluation of fetal erythrocytes in the maternal circulation. It has been of great value in determining the incidence and size of fetal transplacental hemorrhage at various gestational ages, at delivery, and following various obstetric procedures and complications.

Approximately 50% of gravidas have evidence of fetomaternal bleeding during pregnancy or immediately after delivery. The significance of these small fetomaternal bleeding episodes, as we all know, lies in their immunologic potential. Failure to recognize the possibility of these small amounts of bleeding and to initiate measures to prevent sensitization may leave the physician open to legal action in the event that the mother is sensitized, because once the damage is done, it cannot be undone. The cause of massive fetomaternal hemorrhage in most of the reported cases has been unexplained. Reported specific causes include placenta previa, abruptio placentae, trauma, and manual removal of the placenta. In recent years, amniocentesis has become one of the most common causes, and external version has also been reported as a cause.

In the literature I reviewed, most of the babies in these cases died antepartum or very soon postpartum, as was true, in Dr. Hoag's case. I did not find any reports of infants' surviving with significant brain damage. The majority of these cases were apparently acute massive fetomaternal hemorrhage, not chronic. I wish to ask Dr. Hoag whether he has noted the same thing and whether he has found any cases of cerebral palsy, seizure disorders, or impairment of intellectual function attributed to fetomaternal hemorrhage. The more evidence we accumulate to show that damage to the baby's central nervous system can occur before labor, the less vulnerable we will be to lawsuits and their astronomic awards.

Out of curiosity I asked the medical records department in my hospital to pull all cases of fetomaternal hemorrhage for me. Data from only the last 3 years have been entered into the computer. There were no cases of fetomaternal hemorrhage. I next asked for the records of all cases of nonhemolytic anemia in the newborn. Again, there were no cases. I then asked our blood bank how many Betke-Kleihauer tests had been performed in the last 3 years and whether any of them had revealed massive fetomaternal hemorrhage. Fifteen tests had been performed in the previous 40 months, during which time there were 7696 live births. Seven tests showed significant bleeding, the largest being approximately 110 ml. There was no bleeding over 150 ml. Four of the tests were ordered by one obstetrician following elective external cephalic version. I think it is apparent that in my hospital, at least, massive fetomaternal hemorrhage is a very infrequent occurrence or is being missed. I don't know how many unexplained fetal deaths there were in that period, but obviously nobody considered massive fetomaternal hemorrhage as a possible cause, since no one looked for it.

I agree with Dr. Hoag's recommendation that in each case of massive fetomaternal hemorrhage, the umbilical cord should be carefully sectioned to look for thrombosis of the vein. His presentation's greatest value in my mind, however, is that it again directs our attention to the fact that the fetus can bleed into the mother in large amounts and without any external signs that anything is amiss. It is an occurrence that will not be diagnosed if it is not thought of and looked for. Although it may not be possible to materially improve the salvage rates, we should be able to explain some previously unexplained fetal deaths and to absolve the obstetrician of any responsibility for them.

A by-product of my preparation for this discussion was that I delved into the literature on placental pathology, looking for a lesion that would account for this bleeding. In a majority of the cases, as previously mentioned, no placental lesion was found. Reading some of the more recent literature, I found that there is a renewed interest in placental study, with attention directed to the uterine side of the placenta to look for possible defects that might explain otherwise the inexplicable pregnancy complications. Preeclampsia and intrauterine fetal growth retardation are two such disorders in which new information has come to light by the study of placental bed biopsies and occasional cesarean hysterectomy specimens. Older concepts are being discarded, especially concentration on functionally unimportant gross abnormalities, and new emphasis is being placed on more subtle pathophysiologic processes. Such mysteries as preeclampsia and intrauterine growth retardation may actually be due to disorders of placentation in its earliest stages. I quote H. Fox[3] in a recent publication:

The placenta is a vigorous, energetic, versatile organ with a considerable physiologic reserve capacity. Most pathologic lesions of the placenta are functionally irrelevant and it is doubtful if the placenta often, or ever, becomes insufficient. Attention is being increasingly directed to the interaction of extravillous trophoblast and maternal tissues during placentation and it is becoming clear that many of the ills that beset a pregnancy have their origin in an abnormal interrelationship between fetal and maternal tissues during the earliest stages of establishment of gestation.

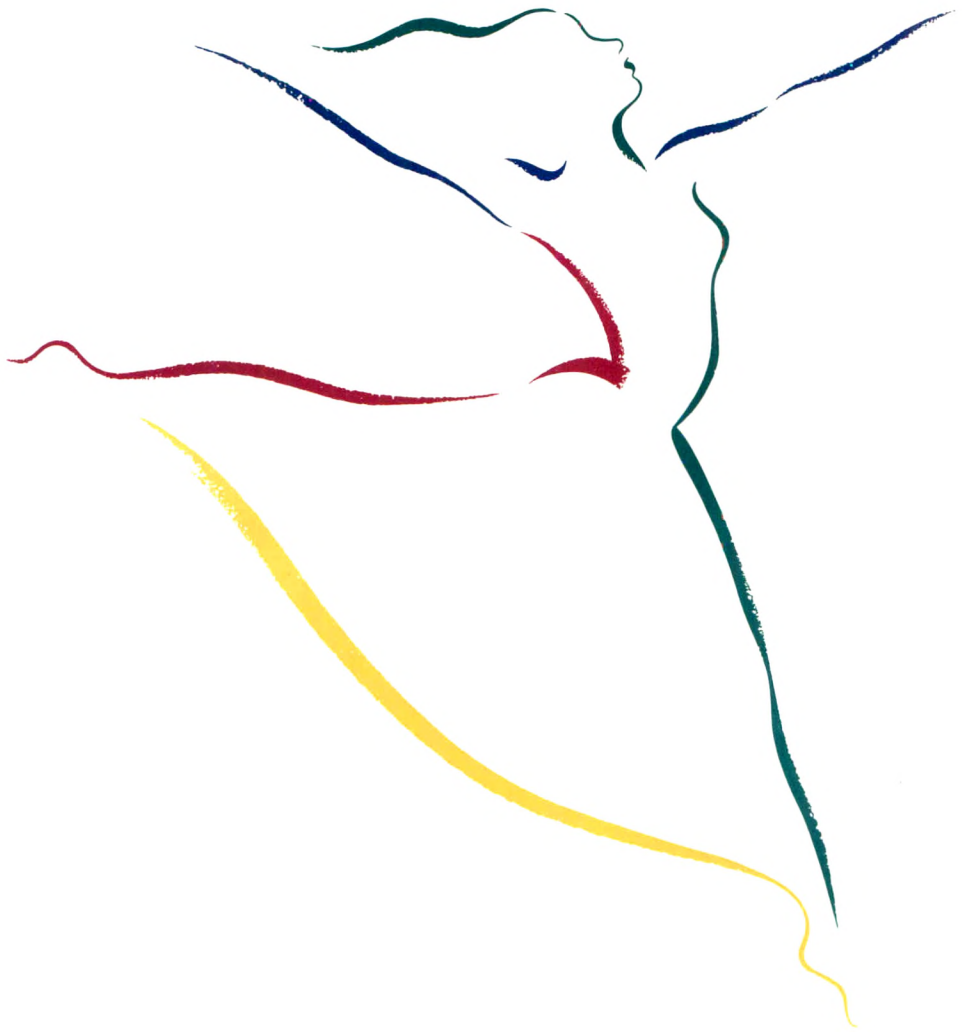
DR. JULIAN PARER, San Francisco, California. I've got two comments. The first is that I know of at least one case of maternofetal bleeding, with a subsequent newborn hematocrit value of 15%, in which there was no sinusoidal pattern at all. And I think it is of some interest that your case also showed a flatness of baseline, as well as a classic sinusoidal pattern. I don't know where this fits into the cause of this sinusoidal pattern, but I just leave you with the comment that it's not always a constant thing.

Now, the second comment I'd like to make is with respect to the tolerance of the fetus for anemia. In slowly developing anemia, as in erythroblastosis, we've noticed fetal hematocrit values, or newborn hematocrit values subsequently projected back to fetal, down to 8%. This is still consistent with intrauterine life and consistent with intrauterine pneumonia, as demonstrated by cord blood gas values. The fetus has a remarkable resistance to slowly developing anemia. These fetuses can still move—not too many of them at such a low hematocrit value, but certainly with a hematocrit of 15% the fetuses can still move. In fact, they may have a respectable biophysical profile, which I think is an indication that the use of this stress test is much more important in these babies who are at risk for severe anemia.

DR. RICHARD PAUL, Los Angeles, California. The case discussion seems to indicate that the patient had noticed symptoms that brought her initially to the hospital some hours before. Then if one speculates about the occlusion of the vein and the possible consequence of that—and then the subsequent patterns and the abrupt problems at the end—the cause was probably hypovolemia. I wonder whether there was any finding at autopsy in the baby's heart. It might relate either grossly to failure or microscopically to some lesions that may have developed during this process, in addition to the findings in the umbilical vessels.

DR. ROBERT GOODLIN, Denver, Colorado. What was the time interval between what looked like a "normal baseline," although sinusoidal, and the delivery of the fetus? I had an unfortunate case in which an amniocentesis showed bloody fluid and in which the fetal heart rate looked worrisome. I thought that we had a relatively adequate amount of time, but I, likewise, delivered a stillborn infant. I had always thought that there would be a time of profound bradycardia before the occurrence of fetal death.



I also wish to comment that, at least in the literature now, there are a fair number of reports of nonimmune hydrops. This problem can also result from fetomaternal hemorrhage and is something we should look for.

DR. HOAG (Closing). One question asked was whether I had observed, in my search of the literature, any correlation of mental retardation, cerebral palsy, etc., with massive fetomaternal bleeding. I did not address that question, and therefore I have no information on that score, although it seems to me, just speculating, that if the fetus were in severe distress over a period prior to delivery, the infant would not be immune to such an outcome.

Dr. Paul, the pathologist's only comment about the child's heart was that the chambers were small, a finding consistent with hypovolemia. He did not find myocardial infarction. I don't know how carefully he looked for it, but he didn't diagnose it.

In reference to Dr. Goodwin's question on the time lapse—this patient was admitted at 1 o'clock in the morning, and we began the process of monitoring her. We delivered her at roughly 5:40 AM, approximately 4 hours and 40 minutes later. The course of events escalated rapidly, and in the absence of any prior history, symptoms, or signs, one found the situation hard to believe, especially at 2 or 3 o'clock in the morning. As the situation deepened and worsened, the tempo increased and led to the emergency cesarean section, which was probably performed too late. Whether the results would have been different—or maybe even worse—if we had operated an hour sooner, I don't know.

New imidazole for vulvovaginal candidiasis

Introducing

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

The Only 3-Day Cream*

*In non-pregnant patients, 3-day treatment is recommended. Treatment may be extended an additional 3 days, if necessary.

Please see brief summary of full prescribing information on last page.

SYNTEX

New imidazole for
vulvovaginal candidiasis

3-Day Cream

The shortest course of the preferred form

New Femstat®

vaginal cream 2.0%

(butoconazole nitrate)

The Only 3-Day Cream

- Symptom resolution comparable to 7-day miconazole cream with only 3 days of therapy.[2]
- Cream—the preferred form for prompt relief of vulvar itching and burning.[1]
- Low recurrence rate at one-month follow-up.
- Minimal incidence of side effects—limited to local irritation.
- Exclusive disposable applicators to enhance patient compliance.

1. According to a 12-month nationwide industry audit (ending October 1985), comprised of approximately 2,000 pharmacies. Vulvar burning occurred in 2.3% and itching in 0.9% of patients on Femstat.
2. Bradbeer CS, Mayhew SR, Barlow D: Butoconazole and miconazole in treating vaginal candidiasis. *Genitourinary Med* 61:270-272, 1985. (Study conducted in non-pregnant patients.)

SYNTEX
SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

New imidazole for vulvovaginal candidiasis

New Femstat® (butoconazole nitrate)

vaginal cream 2.0%

The Only 3-Day Cream

Scanning electron photomicrographs (5000X) of *Candida albicans* grown for 48 hours in serum (left), and in serum with 200 mcg/ml butoconazole nitrate (right).

Brief Summary

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General:
If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient:
Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis:
Animal studies have not been done.

Mutagenesis:
Mutagenicity studies were negative.

Impairment of Fertility:
Animal studies showed no impairment of fertility.

Pregnancy Category C:
Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers:
Use with caution.

Pediatric Use:
Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

COLUMBIA UNIVERSITY
The College of Physicians & Surgeons

The Department of Obstertrics & Gynecology of the College of Physicians & Surgeons and The Presbyterian Hospital

26th ANNUAL REVIEW COURSE IN OBSTETRICS AND GYNECOLOGY

October 27 through 31, 1986
(Monday-Friday, 8:00 A.M. - 5:30 P.M.)

36 Credit Hours, Category 1, A.M.A.'s Physician's Recognition Award; 36 Cognates by American College of Obstetrics & Gynecology; and 36 Elective Credits from the American Academy of Family Physicians.

FEE $635 (residents $325); includes syllabus, luncheons, and refreshments

MORTIMER G. ROSEN, M.D., associates, and the following guest lecturers:

THEODORE BARAMKI, M.D. **HOWARD MINKOFF, M.D.** **CARMEL J. COHEN, M.D.** **MARVIN KIRSCHNER, M.D.**
JEROME BELINSON, M.D. **ROBERT S. NEUWIRTH, M.D.** **ROY H. PETRIE, M.D.** **ROBERT KNUPPEL, M.D., M.P.H.**
FRANK CHERVERNAK, M.D. **STANLEY ROBBOY, M.D.** **GARY HODGEN, M.D.** **BRIAN LITTLE, M.D.**
GERSON WEISS, M.D.

Survey of the major clinical and pathological problems pertaining to the female reproductive system. Designed for practicing clinicians and for candidates for the Board Examinations. Emphasis is placed on the diagnosis and management of obstetrical and gynecological disorders, including infertility, endocrine problems and malignant diseases. A review of gynecologic pathology is included. Modern advances in basic knowledge and application to clinical practice is stressed. The course is divided as follows: gynecological oncology, perinatal medicine, fetal and maternal medicine, reproductive endocrinology and gynecological surgery and infertility. The **Second Annual Raymond L. Vande Wiele Memorial Lecture** will be presented by Mortimer G. Rosen, M.D., on Wednesday, October 29th, at 1:30 p.m.

Contact: Elizabeth C. Gerst, Ph.D., Assistant Dean for Continuing Education, 630 West 168th Street, N.Y., N.Y. 10032; telephone (212) 305-3682.

OBSTETRICS AND GYNECOLOGY PROGRAM DIRECTOR
CHIEF, DIVISION OF REPRODUCTIVE ENDOCRINOLOGY AND INFERTILITY

The Department of Obstetrics and Gynecology, Georgetown University School of Medicine is recruiting for the following positions:

OBSTETRICS AND GYNECOLOGY PROGRAM DIRECTOR, COLUMBIA HOSPITAL FOR WOMEN
This women's hospital is a major affiliate of Georgetown University School of Medicine, Department of Obstetrics and Gynecology. Candidates must be certificated by the American Board of Obstetrics and Gynecology and have subspecialty certification in Maternal-Fetal Medicine.

CHIEF, DIVISION OF REPRODUCTIVE ENDOCRINOLOGY AND INFERTILITY
A full-time faculty position as the Chief, Division of Reproductive Endocrinology and Infertility at Georgetown University School of Medicine. Candidates must be certified by the American Board of Obstetrics and Gynecology and have subspecialty certification in Reproductive Endocrinology.

Please send curriculum vitae, bibliography and letters of reference to:

John T. Queenan, M.D.
Professor and Chairman

TRI-LEVLEN™

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

A LOW-DOSE TRIPHASIC OC WITH THE CONFIDENCE THAT COMES FROM EXPERIENCE

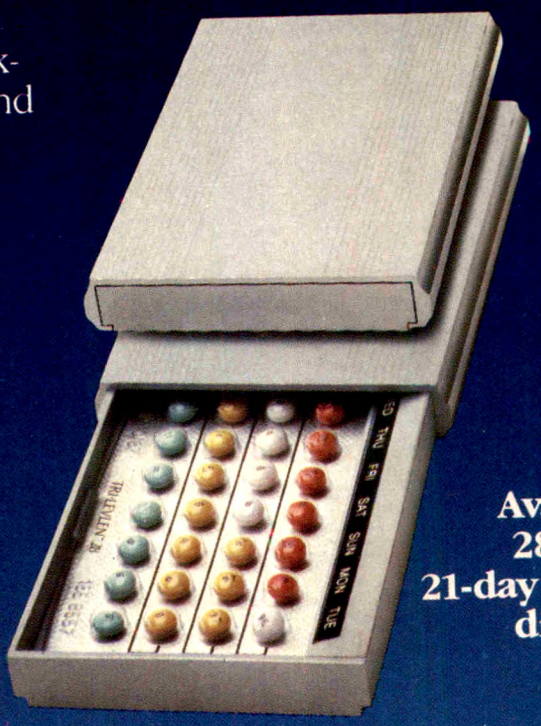
*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

A formulation with the lowest total hormonal dose in a combination OC

Phased doses of both levonorgestrel and ethinyl estradiol

Permits a decrease in total steroid dose without compromising effectiveness.

Low incidence of breakthrough bleeding



A low 5.7% overall incidence of breakthrough bleeding based on 77 U.S. and U.K. studies involving 3,546 women (35,036 total cycles).[1]

Simple first dose/first day start

The first dose is taken on the first day of menstruation. No need to count days or wait for Sunday starts.

Minimal impact on the following metabolic and hemodynamic parameters*

Lipids;[2,3] carbohydrate metabolism[2,3] and blood pressure[1] were not significantly affected in certain specific studies.

A formulation with the confidence of 170 million cycles of experience worldwide

Available in 28-day and 21-day Slidecase™ dispensers

TRI·LEVLEN™28 TRI·LEVLEN™21

BERLEX™ **Dedicated to innovation in OB/GYN medicine**

TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000); the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule: OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

Preinduction cervical ripening with sequential use of prostaglandin E_2 gel

Robert P. Prins, M.D., Duncan R. Neilson, Jr., M.D., Richard N. Bolton, M.D., Carl Mark III, M.D., and Peter Watson, M.D.

Portland, Oregon

Two hundred patients received a prostaglandin E_2–containing gel for preinduction cervical ripening. The gel was administered every 6 hours until a Bishop score ≥7 was obtained or the attending physician deemed induction necessary. Forty-eight percent of the patients labored "spontaneously" after one or more gel applications. The average cumulative change in Bishop score with sequential application of the gel was 2.7. Sequential application of the prostaglandin gel proved no more effective in the process of preinduction cervical ripening than single application of the gel with a similar period of observation. (Am J Obstet Gynecol 1986;154:1275-9.)

Key words: Prostaglandin gel, cervical ripening

Prostaglandin-containing gels for the purpose of cervical ripening are now in widespread use.[1-5] Optimum methods of application, however, have yet to be determined. Previous studies by our group[6,7] using prostaglandin-containing gels determined that cervices ripened to a Bishop score of ≥7 had a much higher incidence of induction success and a lower occurrence of cesarean section. The protocol followed in these investigations allowed for one gel application followed by a ripening period of 12 to 16 hours and subsequent Pitocin induction of labor regardless of cervical Bishop score. On the basis of these studies it was felt that a sequential application of prostaglandin-containing gel might further ripen the cervix and enhance the effectiveness of prostaglandin gel use.

Methods and material

Prostaglandin gel was prepared as previously described.[6] The final concentration was 5 mg of prostaglandin E_2 per 10 ml of gel.

The study group consisted of 200 patients carrying singleton pregnancies and needing induction of labor for medical indications. The patients were assessed before gel instillation on the morning of the day of induction. To reduce bias in the estimation of the Bishop score two examiners evaluated each patient before and 6 hours after each gel application. The average of the two scores constituted the assigned Bishop score.

From The Women's Clinic, Emanuel Hospital, University of Oregon Health Sciences Center.

Presented by invitation at the Fifty-second Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Napa, California, September 29–October 4, 1985.

Reprint requests: Robert P. Prins, M.D., 2220 Lloyd Center, Portland, OR 97232.

After the examination 10 ml of gel (5 mg of prostaglandin E_2) was instilled into the vaginal fornices with a No. 20 red-rubber catheter. The catheter was then withdrawn and the patient remained recumbent for 15 minutes. Maternal vital signs were assessed every 4 hours. Uterine contractions and fetal heart rate were monitored continuously with an external fetal monitor.

The patient was reevaluated every 6 hours after the initial gel application. If the averaged Bishop score was ≤6, gel was reapplied. This protocol was repeated until a Bishop score of ≥6 was achieved or the attending physician determined induction necessary. Oxytocin administered by intravenous infusion pump was then begun. Adequate oxytocin stimulation was defined as firm, regular, painful contractions with an average frequency of one every 3 minutes. Membranes were ruptured with the onset of active labor, defined as progressive cervical dilatation. Failed inductions were defined as those cases where adequate labor could not be established or those where, although adequately stimulated, no progressive cervical change ensued. All data were analyzed statistically by Student's t test or χ^2 with the use of the Edu-Ware Statistics Package 3.0.

Results

The 200 patients consisted of 109 primigravid and 91 multigravid women with an average gestational age of 39.9 weeks. The average gel-induction interval for the study was 14.9 hours; the average Pitocin dose, 13.2 mU/min; and the average length of labor, 8.0 hours. The rate of maximum dilatation in the active phase (used as a clinical assessment of cervical compliance) averaged 4.7 cm/hr. "Spontaneous" labor rates for sequential gel application are shown in Table I. Gel application alone accounted for an induction rate of almost 50%. The average pregel Bishop scores and in-

p Value	NS		NS		NS	<0.05	<0.025	<0.025

terval Bishop scores are shown in Table II. The change in Bishop score was assessed only in those patients not laboring "spontaneously." There were 43 cesarean sections performed in the study group for a cesarean section rate of 21.5%. Twenty-nine of these (14.5%) had as the indication cephalopelvic disproportion; 12 (6%), fetal distress; and two (1%), other indications.

Cervical ripening and labor outcomes differed with gestational age. While there was greater cervical change in the group <37 weeks' gestation, there was a much lower incidence of "spontaneous" labor. The least cervical change occurred in the group >42 weeks' gestation. This group also had the lowest maximum rate of cervical dilatation in the active phase and the highest rate of cesarean section. The proportions of primigravid and multigravid women did not differ significantly among the groups (Table III).

Those patients laboring "spontaneously" after gel application had, on the average, higher initial Bishop scores, shorter labors, and a much lower rate of cesarean section (Table IV).

Primigravid women differed from multigravid ones only in having a lower incidence of "spontaneous" labor after gel application and a lower maximum rate of dilatation in the active phase (Table V).

Those patients undergoing cesarean section for the indication of cephalopelvic disproportion, when compared with all normally laboring patients, had a lower incidence of spontaneous labor after gel insertion, a much lower maximum rate of cervical dilatation in the active phase, and higher infant birth weights (Table VI).

Those patients classified as having failed inductions differed from the remaining study group by having lower pregel Bishop scores, less cervical change, and a much higher dose of oxytocin required to produce adequate labor (Table VII).

There were no maternal or fetal-neonatal deaths in the study group. Maternal morbidity consisted of 16 cases (8%), detailed in Table VIII. Infection and hemorrhage accounted for most of the morbidity. There were five instances of neonatal morbidity: three cases of Erb's palsy, one case of meconium aspiration, and one case of respiratory distress and bronchopulmonary dysplasia in a 1 pound, 8 ounce infant.

Table VIII. Maternal morbidity
(n = 16/200, 8%)

Complication	n
Postpartum hemorrhage	7
Infection	4
Uterine window	1
Abruptio placentae	1
Retained placenta	2
Thrombophlebitis	1

When the outcome of patients in the current protocol was compared to that in our previous study with the use of only one gel application and a 12- to 16-hour delay before induction,[6] no significant differences could be found. Total cervical change remained similar (2.5 versus 2.7) as did the incidence of "spontaneous" labor after gel insertion (46% versus 48%). Failed inductions accounted for 6% of the cases with single gel use and 5% of the cases of sequential gel use. The incidence of cesarean section did not differ significantly.

Comment

The aim of the present study was to assess the efficacy of sequential vaginal prostaglandin gel application in ripening the cervix and promoting successful labor induction. Our results confirm the gel's effectiveness when used in this manner. However, when the results were compared with those of our earlier study, sequential gel application appeared no more effective than single gel application followed by an equal period of observation.

Discussion

Dr. Hedric B. Hanson, Anchorage, Alaska. The problem of medical induction of labor when there is an unfavorable cervix continues to perplex the clinician. The data in the world literature seem to support the premise that the application of prostaglandin E_2 to the cervix promotes cervical ripening and facilitates the induction of labor. Shepherd et al.,[1] in 1981, presented 1000 consecutive unselected cases of induction of labor with the use of prostaglandin E_2 suppositories for medical or obstetric reasons. Only 27% of the entire series required augmentation of labor with intravenous oxytocin, the range being from 9.9% of multigravid women with a favorable cervix to 42.4% of primigravid women with an unfavorable cervix. With an unfavorable cervix, 42% of the primigravid women versus 25% of the multiparous patients required a second inducing suppository. Prostaglandin E_2 suppositories have become routine at London's Queen Charlotte Maternity Hospital, being simple, safe, and highly acceptable to the patients and obstetricans alike in all cases in which a simple amniotomy would not suffice. The overall rate of failed inductions resulting in cesarean section in those patients with an unfavorable cervix has fallen from 42% to 2.5%.[1] Ekman's group[2] in Malmo, Sweden, has demonstrated, in a randomized study, that patients with a highly unfavorable cervix apparently respond best to intracervical application of the prostaglandin E_2 gel. With a relatively ripe cervix there are small differences in efficacy between the intracervical and intravaginal routes of administration. However, this same group warns of potential maternal and fetal side effects that are particularly pronounced with the intravaginal administration of prostaglandin E_2. That intravaginal administration of prostaglandin E_2 gel induces considerable myometrial activity compared with that produced by intracervical administration was objectively confirmed by the intrauterine pressure recordings. The Ekman group achieved cervical ripening, induction of labor, and delivery with an 8% cesarean section rate.[2]

The prostaglandin E_2 gel has not been approved by the Food and Drug Administration. Experimental protocols have been developed at various university and community hospitals. Macer et al.[3] have presented data on the use of 3 mg prostaglandin E_2 suppositories obtained by cutting a 20 mg prostaglandin E_2 suppository into 3 mm chips. The Portland group has documented the effects of prostaglandin E_2 vaginal gel prepared by thawing the 20 mg prostaglandin E_2 vaginal suppository and homogeneously mixing it with a methylhydroxyethyl cellulose gel (tylose). This preparation ripens the cervix, reduces induction failures, diminishes oxytocin dosage needed for induction, and lowers the cesarean section rates.[4] The present article is a companion study of and demonstrates that the sequential application of the prostaglandin E_2 gel appears no more effective than single gel application.

I, however, have some reservations about the study design. The study was designed to evaluate the effects of sequential application of prostaglandin E_2 on cervical ripening. Considering the sequential application of prostaglandin E_2, Why was the intravaginal route chosen over the intracervical route? Why were the second and third applications not placebo-controlled? Considering the cervical ripening, how was the interobserver reliability (Bishop score) studied? Are there more objective methods of evaluating cervical ripening? Was the modified Bishop score proposed by Lange considered? Was sonographic evaluation of the lower uterine segment and cervical changes considered?

Despite my questions, I would again like to emphasize the importance of the work done by the Portland group in documenting the effects of the reconstituted prostaglandin E_2 gel on cervical ripening.

4. Prins RP, Bolton RN, Mark C, Neilson DR, Watson P. Cervical ripening with intravaginal prostaglandin E_2 gel. Obstet Gynecol 1983;61:459.

Dr. Robert Sack, Whittier, California. Dr. Prins, I am concerned about one thing. There were 16 complications, and three of them were cases of Erb's palsy, that is, 70% of the complications were Erb's palsy. I would like your response.

Dr. William Graves, San Francisco, California. Dr. Prins said these were all medically indicated inductions, and I think the value of the written article, at least, would be enhanced if he could break these down a little bit for us. I would suggest he use the same two observers when the gel is applied sequentially. If we are going to present any studies on the induction of labor, probably we really should separate parous patients from primiparous patients. The real value of anything that can enhance labor is particularly going to be present in the patients at 42 weeks' gestation, and I hope that the written article will establish this group and

evaluate it separately. This is a worthwhile study on a very important obstetric subject.

Dr. E. Paul Kirk, Portland, Oregon. Dr. Prins emphasizes the well-known fact that difficult things in obstetrics are difficult to deal with.

I was interested that even in those two subgroups where it might appear that the outcome would be more advantageous, namely, those patients who went into "spontaneous labor" after prostaglandin administration and the multiparous group, there were high cesarean section rates, one of 14% and one of 17%. These findings are somewhat inconsistent with other reports for those subgroups, and I wondered whether there was any explanation for that. I would like to ask specifically whether women who had a previous cesarean section were excluded from this form of induction.

Dr. Edward Quilligan, Sacramento, California. Hypertonus has been frequently mentioned as a complication of vaginal prostaglandin. Would Dr. Prins discuss the frequency of hypertonus and whether any instances of fetal distress were associated with hypertonus.

Dr. Prins (Closing). The study design of intravaginal gel was designed essentially to compare sequential versus single use. In previous studies we looked at whether the gel was effective and performed studies in which we used placebo gels matched against prostaglandin E_2–containing gels. We established that, in our hands and with our preparation, the gel appeared to work. That is the reason we did not pursue any placebo-controlled experiments.

Ulmsten et al. have shown that intracervical application of 500 μg of prostaglandin E_2 is probably more effective than vaginal application. It is, however, more difficult to do. We currently have about 100 patients in our study of intracervical application versus intravaginal application.

The reason for using the older Bishop score was twofold. First, it has allowed me to compare my data with those of the European investigators, who until the early 1980s were the only people working with prostaglandin gel as a ripening tool. Second, it allowed me, once I started, to compare my data, as I have done here, from one study to the next. That is the rationale for the continuation of the perhaps outmoded Bishop scoring system.

The issue of ultrasound is an interesting one. It certainly has been used for diagnosis of incompetent cervices, but the cervix, with as much water content as it has at term, does not lend itself well to this modality. Although I think dilatation and effacement could be seen to a degree, the measurements, although more precise, would be no more accurate in determining whether the cervix is ripe or not ripe.

We had three cases of Erb's palsy in 200 patients. It was indeed three of the 16 in our complication group and I think reflects the fact that we were inducing a large number of high birth weight postterm infants.

The majority of our patients had labor induced because of postdatism; large for gestational age infants; diabetes, insulin-dependent or non-insulin dependent; hypertension, pregnancy-induced or chronic, and other maternal indications.

I had hoped that the examiners would be the same, but they were not. I do not have absolutely accurate records, but at least 60% of the time the same two people examined the patient, and there was always one person in common for each examination. When the 42-week group was separated out, we found that they had a high rate of cesarean section, less cervical change, and a much lower rate of cervical change in the active phase. The "high rate of cesarean section" in the study is something that we simply have to live with. In our initial study of prostaglandin in a population that was high risk with unfavorable cervices and with the use of placebo controls, our cesarean section rate was around 40% in the Portland area. I do not know whether that is right or wrong but it is a fact. With the use of prostaglandin gel in these difficult circumstances, our cesarean section rate has almost been halved. Whether it can be changed more than that I do not know.

Dr. Kirk picked up on the fact that there was one repeat cesarean section in the group, which I had included in the complications. We have a separate protocol in Portland for using prostaglandin gel for preinduction cervical ripening in cases of prior cesarean section. I personally think it is an ideal tool for this. This woman was inadvertently entered into the study and I did not feel it was fair to remove her. She was gravida 2, para 1, with a prior cesarean section. She did not have spontaneous labor with the gel and underwent approximately 8 to 9 hours of Pitocin stimulation. A repeat cesarean section was performed because of cephalopelvic disproportion, and she was found to have a uterine window at the time of cesarean section.

There were no cases of hypertonus in these 200 patients. We have had cases of hypertonus in Portland when the gel was used, and they have occurred with what I would term the injudicious use of the gel in women with very ripe cervices (Bishop scores of ≥ 8) and in grand multiparous patients with very ripe cervices. Before the gel was well established for use in the Portland area, Pitocin and gel were on occasion used together. The combination of oxytocin and postaglandin gel is almost a guaranteed hypertonus situation.

On the origin and progression of human breast cancer

Hanne M. Jensen, M.D.
Davis, California

The mature human female breast contains thousands of hormone-sensitive, potentially milk-producing microorgans, called lobules. In the nonpregnant state they vary in size from 1 to 8 mm but most are 1 to 2 mm in diameter. Each lobule is drained by a terminal duct attached to the main duct system. It is called the terminal ductal-lobular unit, which normally regresses at menopause. Most breast diseases except papillomas in major ducts arise in terminal ductal-lobular units. Disease processes such as hyperplasias and neoplasia alter the terminal ductal-lobular units to such a degree that conventional light microscopic appearances make the structures appear as though they were ducts. However, the basic microarchitecture in three dimensions is preserved, proving the origin of cancer is the terminal ductal-lobular unit. (Am J Obstet Gynecol 1986;154:1280-4.)

Key words: Breast cancer, origin, progression

Development of breast cancer is a common occurrence in the human female. It usually presents as a firm mass and most often is detected by the woman herself. At this time the disease has usually progressed to the invasive stage when cure is less likely. How can the obstetrician and gynecologist who cares for women in their younger years of life, when the disease is in a precancerous phase, possibly detect the women at risk? Mammography is valuable because minute irregular calcifications are seen in the x-ray films, attesting to focal areas of necrotic tissue that have imbibed calcium. Such calcifications occur within foci of ductal carcinoma in situ, the preinvasive stage of the disease.

Might it some day be possible to detect the disease in its precancerous stage and intercept it with some form of treatment so that the illness would be arrested at this phase of development? What is known about the origin and progression of breast cancer?

In rodents the mammary fat pads are so thin that they can be stained in toto and the fat can be dissolved so that an entire gland with its branching duct tree can be seen beautifully in three dimensions. It occurred to Dr. Sefton Robert Wellings who had studied precancer in the mouse mammary gland for many years that a study on the microarchitecture of the human mammary gland might elucidate new knowledge about breast cancer in women. Dr. Wellings obtained a contract from the Breast Cancer Task Force in 1967. I joined his research program in 1969 and remained with the study until 1975.

Material and methods

Human mammary glands from 67 autopsies, in which no history of breast disease was noted, served as controls. Fifty-two mastectomy specimens with cancer or contralateral to a previous breast cancer constituted the study group.

Formalin-fixed, whole breasts were sliced on a butcher's meat slicer into 2 mm thick slices in the parasagittal plane. The slices were stained with hematoxylin, washed in water, dehydrated in increasing concentrations of ethyl alcohol and acetone, and finally impregnated with methylsalicylate to diminish light refractions. After the slices were placed in plastic bags containing methylsalicylate, they were viewed at two to 10 times magnification in a dissecting microscope.

Any abnormal structure that had a three-dimensional appearance different from the normal was isolated from the slice and photographed in its entirety at 2 to 10 times magnification. The abnormal structure within the isolated piece was studied under the light microscope after conventional processing for light microscopy with paraffin embedding, 7 μm sectioning, and staining with hematoxylin-eosin stains. The microarchitecture seen three-dimensionally in the photograph was compared and correlated with the histopathologic structure seen in two dimensions in the light microscope. We thus learned that the origin of breast cancer is distal to the branching duct tree.[1] Since all lesions within a given breast were studied, content of disease could be measured in quantity and quality.[2] A grading system for lesions deemed precancerous was devised.[2]

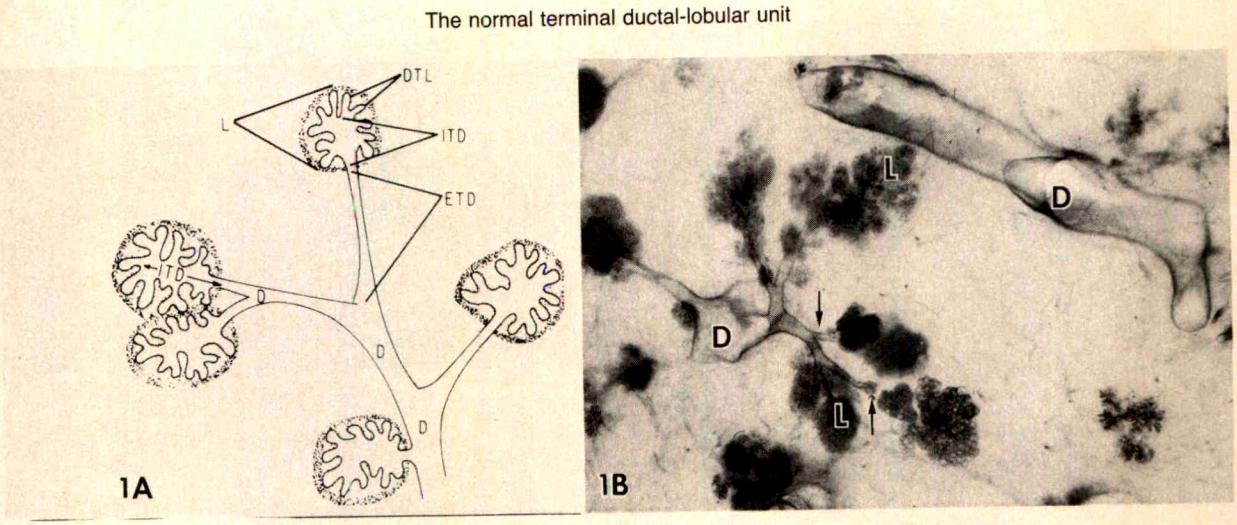

Fig. 1. *A*, Schematic drawing. Ductules *(DTL)* arise from the intralobular terminal duct *(ITD)*. The extralobular part of the terminal duct *(ETD)* connects to the duct tree *(D)*. *B*, Breast slice. *DTL + ITD* constitute a lobule *(L)*. *Arrows* point to *ETD* draining into *D* (×5).

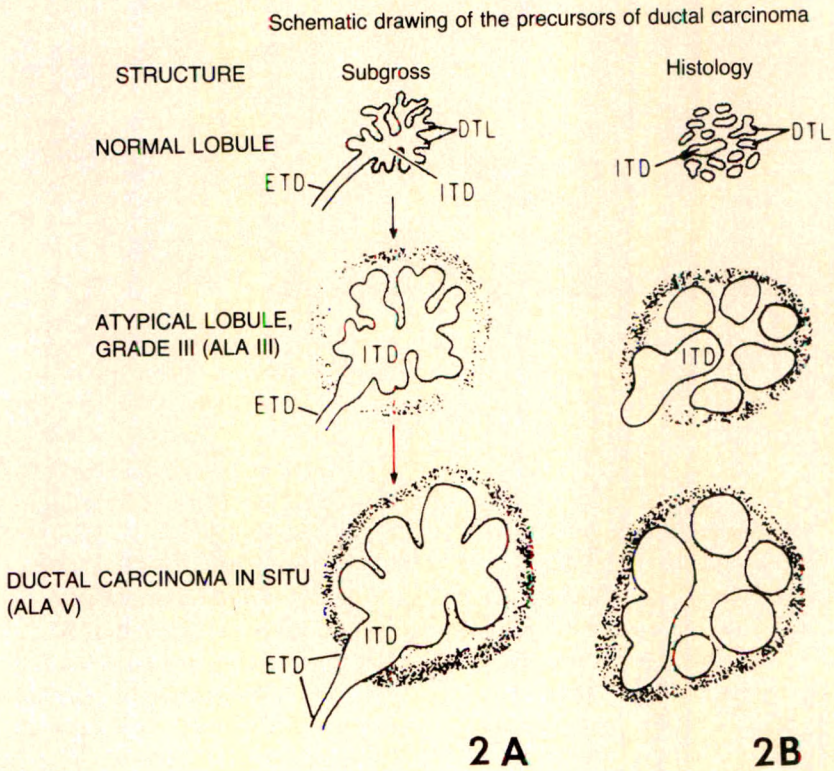

Fig. 2. *A*, The delicate ductules become increasingly coarser as a lobule becomes increasingly more atypical. The terminal ductal-lobular unit is still preserved as a distinct entity. *ALA*, Atypical lobules type A. *B*, In the corresponding histologic two-dimensional appearance the ductules eventually reach the size of small ducts. In such preparations it is hard to appreciate that each constellation in fact represents a terminal ductal-lobular unit.

Results

The microarchitecture of the normal breast parenchyma is very beautiful. The lobules cluster like flowers on the branching duct tree (Fig. 1, *A* and *B*). Each lobule is drained by its own terminal duct that is connected to the duct tree. Since we learned that disease usually occurs within a given lobule and its terminal duct, it was called the terminal ductal-lobular unit.[2] Terminal ductal-lobular units are hormone-sensitive, potentially milk-producing glands that vary from 1 to 8 mm in diameter in the nonpregnant state. Most are <2 mm in diameter. Each breast contains thousands of terminal ductal-lobular units. From the intralobular part of the terminal duct, branching test-tube–like ductules arise (Fig. 1, *A*). Each terminal ductal-lobular unit can be likened to a surgeon's glove with 50 fingers. Lobules normally regress at menopause, leaving stubby small terminal ducts connected to the duct tree. However, in cancer-associated breasts, terminal ductal-lobular units often remain well developed beyond age 55.

Certain lesions formed a morphologic continuum between normal lobules and ductal carcinoma in situ when their microarchitecture (Fig. 2, *A*) and histopathologic structure (Fig. 2, *B*) were correlated. They were called atypical lobules type A.[2] Fig. 3, *A* and *B*, and 4, *A* and *B*, illustrate grade I and grade III lesions on these altered terminal ductal-lobular units. These lesions were believed to be precancerous. Statistical anal-

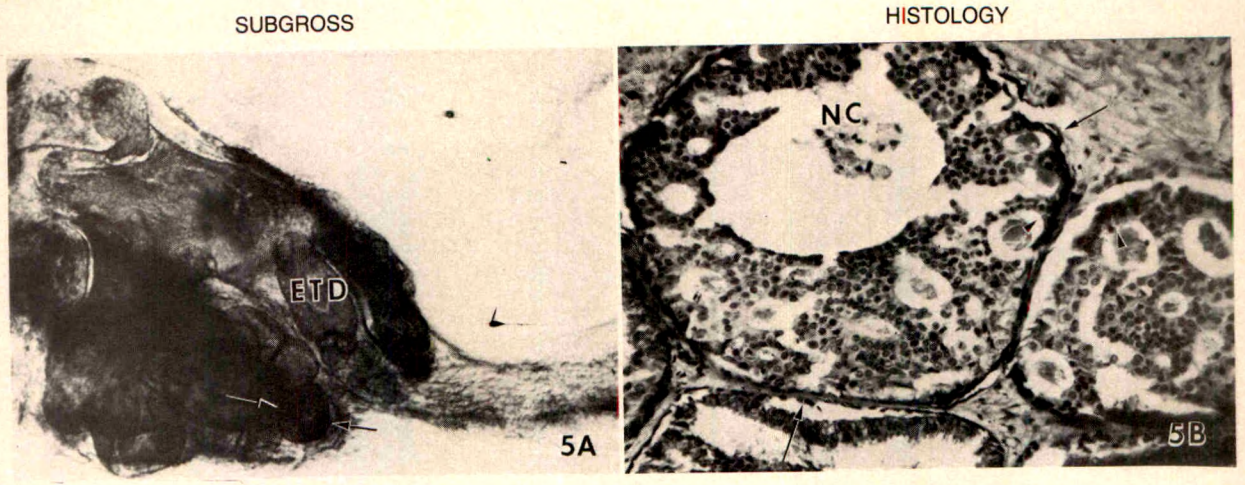

Fig. 5. *A*, ALA V (Ductal carcinoma in situ). *Arrows* point to a large cellular ductule. The *ETD* is distended with cells. (×13.) *B*, ALA V. One ductule outlined by *arrows*. It is distended with cells. *Arrowheads* point to cartwheels. Necrotic cells *(NC)* are present in the lumen. (×125.)

yses disclosed them to be cancer associated.[3] They were more abundant and of a higher degree of atypia in cancer-associated breasts.

In situ ductal carcinoma is found in terminal ductal-lobular units.[1] Multiple foci are commonly scattered throughout the breast.[2] The microarchitecture is grossly distorted into a coarsely lobulated structure, but the entire lesion still maintains the basic appearance of a terminal ductal-lobular unit with a delicate terminal duct (Fig. 5, *A*). In conventional light microscopic preparations the ductules are so big that they look like ducts (Fig. 5, *B*).

If a terminal ductal-lobular unit shows evidence of disease, it is usually of the same type and to a similar degree throughout all the ductules belonging to that terminal ductal-lobular unit. It was therefore postulated that a terminal ductal-lobular unit is of monoclonal derivation and that it originates from a growth zone, much as the way a hair bulb forms a hair.[4] In cancer-associated breasts where cell proliferation within terminal ductal-lobular units may be very active, cells pile up as plaques or as papillomas within the terminal ducts close to the lobule. Therefore it was hypothesized that the growth-zone for a given lobule is located at the interphase between the intralobular part of the terminal duct and the extralobular part of it.[4]

Comment

It had been realized many years before our research was undertaken that three-dimensional studies of breast tissue might cast new light on the pathogenesis of breast cancer; Parks[5] suggested that breast cancer originates in the terminal ductal-lobular unit.

It would be logical that the biologically active part of the breast parenchyma, the terminal ductal-lobular units, would be the site of origin of breast cancer, since they are composed of labile cells with constant cell turnover. Throughout the body it is the labile cell populations that are prone to cancerous transformation such as the cells lining the gastrointestinal tract, the respiratory tract, the genitourinary tract, the skin, and the bone marrow.

Our morphologic study indicated that the cancerous breast is diffusely afflicted with hypercellular changes in terminal ductal-lobular units, which we called atypical lobules type A. A large study was undertaken in which women who had undergone breast biopsies years before were subsequently investigated for development of breast cancer. The women with grade III and grade IV atypical lobules type A in the earlier breast biopsies developed breast cancer more frequently than expected.[6]

The fact that histologically normal-appearing terminal ductal-lobular units tend to persist beyond the menopause in women with breast cancer may be extremely important in understanding the causes of breast cancer. Do women at risk for breast cancer maintain terminal ductal-lobular units because of continual hormonal stimulation of the units or are terminal ductal-lobular units at risk endowed with more hormone receptors?

Terminal ductal-lobular units can be isolated as distinct entities after supravital staining. The cells do not appear damaged by the staining, judging from transplantation studies[7-9] or from tissue culture studies.[10] The biologic behavior of terminal ductal-lobular units should undergo extensive research so that we may gain further knowledge of the "seed" in which breast cancer starts.

TRANSACTIONS OF THE FIFTY-THIRD ANNUAL MEETING OF THE CENTRAL ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

The Golden Thread

Presidential address

George D. Malkasian, Jr., M.D.
Rochester, Minnesota

In 1859 Charles Darwin published his book, *On the Origin of Species by Means of Natural Selection or the Preservation of Favoured Races in the Struggle for Life.* The first few chapters describe artificial selection by man as well as natural selection as a consequence of the struggle for existence. The latter, natural selection of fortuitous variations, gave a scientifically satisfactory explanation of evolution without any necessity for miraculous interposition or supernatural interference with the ordinary laws of nature. This then led to extensive studies of responses of individual organisms to their environments and of specific effects of the environment on species. A short while later Alfred Russel Wallace extended Darwin's thoughts with the observation that man, with the use of the specialized human brain, had avoided the problems that had befallen so many other species. This brain has been used to develop what we have come to accept as science with all of its good and, at times, bad prospects.

A bit over 100 years later, Eiseley[1] noted with fascination that on the great stage of evolution was a play with a strange quality about it: most of the characters had begun in generous latitudes of space and ended by being pinched out of existence in a small corner with no outlet. Biologic evolution was then defined by an endless series of specializations. For many species this specialization became the road to extinction.

It is relevant to quote Eiseley[1]:

Civilized society, confronted by innumerable inconsistencies and strains, begins to knock and vibrate like an overheated motor. The long, slow turns of world-time as the geologist has known it, or the invisibly moving hour hand of evolution perceived only yesterday by the biologist, has given way in the human realm to a fantastically speeded-up social evolution induced by industrial technology. So fast does this change progress that a growing child strives to master the sociological mores of a culture which might, compared with the face of past history, compress centuries of change into his lifetime. I myself, like many among you, was born in an age which has already perished.

In an essay on how to deal with progress in the Nuclear Age, Teller[2] stated,

One proposal has been a simple one; I have even found people who call it a logical one: Progress has led to danger; let us stop progress; if possible, let us turn the clock back . . .. As a man who has tried to be an educator, a man who has dabbled in research, I know that to learn is difficult, but I know also that to unlearn is impossible. I am furthermore quite convinced that not only can the clock not be turned back but it cannot even be stopped.

In Abraham Lincoln's words, "The dogmas of the quiet past are inadequate to the stormy present. As our case is new, so must we think anew and act anew."

For many years, health care systems have adapted to the needs of the time. What is new is the rapidity with which we are being asked to change. We can choose to try to go back to the good old days. We may elect to resist change—inviting with this the extinction of our species. Finally, as obstetricians and gynecologists, we can adapt in order to achieve new systems for delivery of health care.

We, in the medical field, have long believed in certain basic values: dedication to meeting patients' needs; dedication to social responsibility; and, above all, the Golden Thread we have established and clung to while adapting to change, dedication to high-quality medical care. Our constant attention to high quality is the very strength of health care as it exists today.

From the Department of Obstetrics and Gynecology, Mayo Clinic and Mayo Foundation.
Presented at the Fifty-third Annual Meeting of The Central Association of Obstetricians and Gynecologists, New Orleans, Louisiana, October 10-12, 1985.
Reprint requests: G. D. Malkasian, Jr., M.D., Mayo Clinic, 200 First St. SW, Rochester, MN 55905.

To analyze the challenge of change, Cooney[5] noted that the current strengths of American health care come from the existence of excellence, but there currently is in progress a revolution that is unique in terms of size, rapidity, strength, and publicness in our present health care delivery system and is distinct from the evolutionary process. The following are his major points of discussion: "(1) the results of inevitable revolutionary excesses on individuals and institutions; (2) ethics and medical-care technology; (3) cost of care and its effects on access to care; and (4) the health service and resource disproportions latently inherent in our population." To these, we should add (1) undergraduate medical education and residency training, (2) medical professional liability problems, and (3) individual attitudes and practices concerning health.

This is a list familiar to all of us and usually it is only discussed from its negative aspects. Just as the news media, with its Dickensian view, rarely reports beautiful summers or happy days, we rarely look for a positive side to these changes. I hope to point out before we conclude today that many positive things have evolved from our addressing and adapting to the demands presented by the points mentioned above, and that the Golden Thread, although stretched and at times tried to its utmost, remains intact.

The inevitable revolutionary excesses

The inevitable revolutionary excesses that were to try our ability to provide high-quality medical care began with federal action in the 1960s. It was then that we learned that federal priorities are statements, documents, speeches, etc., whereas federal policy is dollars, budgets, and budget justification. The early priorities of those years were to provide the greatest good for the greatest number. The political banner that was raised read "medical care is a right." The political priorities in 1985 still are increased access to quality care and increased knowledge of disease and its prevention. At the same time they include efforts to decrease the costs of delivering that care and of discovering those facts.

The policies of the 1960s led to annual expenditures for health care in the United States of $12 billion in 1960 and of $387 billion in 1984 (12% of the gross national product). The positive side of this expenditure is that increasingly complex procedures have become available to an increasingly larger number of people who could not afford them heretofore. The medical system evolved and was able to expand its services—physically, technically, and with appropriate well-trained personnel. The system expanded under the direction of knowledgeable health care planners who had quality care in mind. Today's policies should be implemented by similar trained personnel prepared to accomplish the forced consolidation.

In 1985 the priority for the thinking person has changed to "the greatest good for the greatest number *with the funds that are available,*" and we now debate whether all-inclusive medical care is a right or a privilege. If we stand by its being a right, then there must be free access for the entire population for all medical care. Is this not similar to the lesson we were taught by OPEC? Medical resources, like oil resources, are limited—they are not infinite as our political associates would lead their electorates to believe. Put another way, can quality care be available to all without loss of access or loss of quality? I believe the answer to both is Yes, with the proper implementation of preventive health care that can be of high quality and can strengthen the Golden Thread.

Ethics and medical care technology

Ethics and medical care technology have become increasingly intertwined. It is interesting that, in a time when we have achieved mastery over so many things in our physical environment, this mastery in itself leads to the need to involve the philosopher, the ethicist, and the clergy. We must involve these disciplines as we apply new science to our practice. There are areas in our specialty that need such input—for example, ultrasonography with its ability to diagnose fetal intrauterine problems; as a consequence of this ability, the development of intrauterine surgery; in vitro fertilization with its spin-offs of surrogate ovum transfer and surrogate ovum fertilization and transfer; cryopreservation of fertilized ova; amniocentesis for diagnosis of genetic or neural tube disorders; fetoscopy for visualization and diagnostic evaluation of the fetus; chorionic villus biopsy for evaluation of chromosomal anomalies; chemotherapy of gynecologic malignancies with agents known to carry with them the risks of future leukemias; the use of gonadotropin-releasing hormone to regulate the anterior lobe of the pituitary; the entire topic of delivery decisions made on subtle changes and interpretations of fetal monitoring strips; and the dilemma of clinical research with its goal of improved clinical outcome for various diseases.

We have accepted the science of these changes quite readily, and the techniques have been applied to our practice, adding further to the excellence and quality of care. However, the resolution of the ethical issues has lagged far behind. It is not only the physicians who are in this situation. At a recent conference I attended in Albany, New York, some of the nation's leading ethicists were present, and there was no agreement among them on any issue discussed. Neither the evolution nor the revolution of technology has been accompanied by

an advance in ethics—a major loss to our patients. It remains then for the individual clinging to the Golden Thread of quality care to provide the integrity and moral responsibility for the best application of these techniques.

Cost of care and its effects on access to care

As the costs of care become an increasingly important item, they must be continually evaluated for their effects on patient access to the Golden Thread. Reviewing National Cancer Institute grant budgets is a useful method of comparing costs of health care. It quickly becomes evident that (1) costs are not similar throughout the nation, (2) they are significantly higher in some areas than in others, and (3) they continue to increase at a rate greater than that of general inflation. The prophets of gloom would predict a headline reading "No funds available for quality care, research, teaching, or advanced technology." If we do not hear the voice of change, this headline may indeed appear. Institutions, as well as individuals, have an instinct for survival and many not-for-profit institutions are turning into corporate entities and are becoming at least partially, if not entirely, for-profit operations.

Some view the changes as tremendously creative.[3] These changes include innovative executive management that supports creativity, marketing, and total for-profit management. Philip Birnbaum, George Washington Medical Center's dean of administrative affairs, emphasized the need for new capital in solving a hospital's problems. For example, his institution's charitable contributions have decreased as a percentage of hospital income, from 21% in 1968 to 4% in 1981. In the same period, governmental contributions dropped from 23% to 12% and hospital debt as a percentage of income rose from 38% to 69%. Not-for-profit institutions do not have the same leverage to raise capital that for-profit corporations have. For example, the former can sell bonds to raise relatively small quantities of money, but the latter can sell stock, thus obtaining a greater number of dollars from the capital market. These institutions have reached innovative agreements with for-profit corporations to maintain control of teaching, research, and indigent care at or above present levels.

Those opposed to for-profit management suggest that the poor will be eliminated from consideration in these contracts. The 1984 statistics available suggest this is not the case. For example, 4.4% of the gross patient revenues of tax-paying, for-profit, investor-owned hospitals went to charity care and bad debt—a percentage exactly the same as that among private, not-for-profit institutions. This suggests that there has been no decreased access to dollars for providing care for the indigent in these institutions.

Other positive institutional innovations, although at times cumbersome, have been strict utilization reviews, sharing of expensive technologies, and specialization in services for which they are uniquely fitted.

While maintaining quality care, physicians have responded by performing more workups and operations as outpatient procedures and, when possible, avoiding weekend hospital admissions other than for emergencies.

During the past year the rate of health care inflation dropped to 9.1% from a previous high of 13.9% in 1982 and an average of 12.7% for the previous 14 years. This occurred during the first year that the system of diagnosis-related group payments was implemented.

A freeze of physicians' fees has also been implemented. But physicians have not been singled out for wage freezes; current legislative proposals are aimed at also freezing Medicaid administrative costs. This is to be achieved by limited federal administrative grants to states rather than open-ended state entitlements.

The medical care system has shown that it can adapt to the policies and priorities of federally mandated change and still provide quality care.

The health service and resource disproportions latently inherent in our population

Disproportionately expensive health care needs of small segments of our population are raising serious questions about our ability to address these needs and still provide quality care for the population at large.

Current indications are that four technologies—kidney dialysis, coronary bypass, infant intensive care, and artificial hearts—could account for $9 billion in annual expenditures. These certainly represent inequities in cost and present us with another decision: the continued use of developed technology as a criterion of high-quality care. It has been repeatedly shown, for example, that if we as obstetricians are able to maintain pregnancies in utero for longer periods when premature labor threatens, the cost of the total care for that mother and infant is less than if delivery is premature. In our area the difference between maintaining a pregnancy in utero rather than in a neonatal intensive care unit is currently about $900 a day.

Unfortunately, medicine is often compared to industry, in which technologic advance means doing things faster, more efficiently, and more cheaply. This is not true in medicine, and the advances tend to become more highly specialized rather than broadly based. However, these advances have led to increasingly more accurate diagnosis, to prolongation of life, and to cures for many diseases. These technical advances continue to reinforce our Golden Thread by producing high-quality care.

Technology as it is today, without further refinement, is consuming a larger and larger proportion of the health care dollar. As the third-party payers consider cost containment and all of its implications, it behooves us to use these advances wisely, to educate our patients as to their uses and purpose, and to educate our trainees to use them appropriately. This may allow us, rather than a third-party payer, to determine who receives what services.

The largest concern regarding disproportionate care is the increasing percentage of the population over 65 years of age. As a group, these people present specific problems that we, as gynecologists, are trained to care for and to do it better than some other specialists—osteoporosis prevention, problems associated with pelvic relaxation, and preventive observation for reproductive organ malignancies, to name but a few.

Undergraduate medical education and residency training

The Golden Thread has remained evident in the arena of undergraduate medical education and residency training. But through the years, social and political pressures have led to a demand for a greater number of physicians, a greater number of primary-care physicians, and a change in distribution of physicians to provide better care to a greater number of people.

In 1965 there were approximately 292,000 physicians in the United States, and there was a perception that more were needed. The profession and its schools responded, so that by 1982 there were about 502,000 physicians. Indeed, the response to the perceived problem was so positive that the same forces that initiated the demand now state there are 50,000 too many physicians at the present time. Despite the stated excess, new loan guarantees are available to 12,500 students and revolving loan funds to 38,500 others.

The federal government has defined the primary-care specialties as internal medicine, pediatrics, and family medicine. On the basis of this definition, the number of primary-care specialists has risen in those same years from approximately 126,000 to 174,000. Furthermore, a 1980 Rand Corporation study[4] has shown a significant change in the distribution of physicians from the metropolitan to the nonmetropolitan areas, so that smaller and smaller towns are acquiring Board-certified specialists who previously were unavailable to them locally.

It is currently stated in H.R. 2699 that it is the "explicit congressional policy" to provide for the training of increased numbers of physicians in primary care. There are currently 15,800 Board-certified obstetrician/gynecologists, and 4800 residents are in training. The number entering training has stabilized at 1200 per year and has remained stable since about 1978. The number of training programs has stabilized at approximately 300 in the United States, but this is a decrease from a high of 483 in 1963. A bill currently in Congress, S. 1210, would, among other things, establish a National Council on Graduate Medical Education which would be responsible for allocating quotas to primary-care specialist programs, perhaps at the expense of other types of specialists. This does indeed address quantity and perceived needs and services, but it does not recognize that the best quality care is provided by completely educated physicians.

Our specialty has addressed the issue of quality training by development of increasingly rigid standards for training programs, continued monitoring of the product of these programs, recertification, and provision for easy access to continuing education of high quality—that is, continuing reinforcement of the Golden Thread.

Medical professional liability problems

The heaviest strain on the Golden Thread has come as a result of medical professional liability problems. In 1975 when one in 20 practicing physicians was being sued, a crisis appeared in regard to liability premiums. Like many crises, some immediate actions slowed the increase in costs and in number of suits but did not stop the trend. Today, one in five practitioners is being sued, and the costs are escalating astronomically.

Halley[5] summarized the situation well:

> Today we do know more about the problem, but reasonable minds still differ on its precise definition. It is not primarily a problem of substandard health care practices, solvable through risk management or disciplinary action against providers. It is not primarily a controversy between physicians and trial attorneys, or between health care providers generally and the legal profession, although reports and news media coverage of events may convey this interpretation. It is not primarily a problem of the insurance industry, manifested by rising premiums, although this sector is certainly involved, as are the economy, state legislatures, state regulatory agencies, and the federal government. It *is* primarily, however, a problem of patient injuries, real or imagined, arising out of or in the course of health care delivery, and at times resulting from health care providers' negligence (Report of the Secretary's Commission on Medical Malpractice. Washington DC; Dept. HEW, January 16, 1973). It is a problem of personal injury to patients in the environment of high technology–modern health care, multiple treatment modalities and drugs, an astronomical number of decisions or individual judgments for delivery or non-delivery of care, and the occurrence of sub-optimal or bad results or treatment failures, sometimes in patients who formerly would not have survived.

The tort system, which was based on negligence and compensation for it, was expected to influence behavior

by inflicting financial loss. However, the emergence of liability insurance spreads this cost, and the impact has been diffused. The system further places demands on the physician for 100% good results and absolute safety. It also assumes it can identify the one at fault, provide a fair trial by peers, and influence behavior by financial impact if a culprit is found guilty. Now, with the application of strict liability by many states, this is no longer a functioning system. For example, in some states even though one may be judged to be only 1% or 2% at fault, if the one responsible for the rest cannot pay the entire judgment, it falls on the minor loser. The tort system is neither prompt nor efficient, and it does not provide for most of the money to go to the injured party.

Solutions proffered include (1) medical adversity insurance; (2) some form of no-fault insurance; (3) programs like workman's compensation; and (4) extensions of legislation such as exists in California with a sliding scale for attorney's contingency fees, a $250,000 limit on noneconomic (pain and suffering) awards, consideration of a claimant's other sources of compensation for injury, and periodic payment for large awards.

As the litigious attitude has expanded in our society, several other major groups—industry, the insurance business, and government—have been affected. With government now affected, the taxpayer has become the new "deep pocket," and people are becoming more aware of the overall problem.

Litigation has caused our Golden Thread to become frayed and strained to its utmost, but I sincerely believe it has not lost its continuity. Several positive elements have emerged from this as part of today's medical practice. There is increased documentation and detailing of procedures, events, and results. There is more informational dialogue with patients. Consultative services are better utilized. There is better adherence to current standard practices. There is more attention paid to better postgraduate education, licensure regulation, and hospital staff appointments. The American College of Obstetricians and Gynecologists has undertaken a pilot study with the sole purpose of evaluating risk factors within a hospital setting, and it is now training physicians to be involved in these systems of evaluation. All of the above do indeed add to costs; but as we are aware, fine-tuning a system generally costs more than the initial system, and the society in which we live already pays for it in many areas of government and industry.

Individual attitudes and practices concerning health

The Golden Thread has been spun by the medical community and sought after by the population at large with little concern on their part as to how they, as individuals, might improve their own health. American industry has paid a heavy bill for medical care for its employees, and these employees in turn have used the system heavily. Because of significant costs, industry now wants its employees to know there are choices that they can make. Health promotion and preventive efforts are being undertaken to change individual attitudes and health care practices. These include programs on smoking cessation, drug and alcohol abuse, and nutrition.

These are areas in which we, as physicians, have been involved to some degree in the past. It should come as no surprise that with the government priority on preventive medicine we will be asked to do more of these things. We face increasing competition as providers of this information. These programs fall into the catch-all of "continuous care," and as we are all aware, there is no generally accepted definition of the continuous-care provider.

Our Golden Thread has led us in the past to be involved in teaching patients on a one-on-one basis and somewhat on a group basis. Some medical societies now have undertaken the changing of attitudes on a mass-media basis with sound, useful information of a complete, well-founded nature, not an advocate's narrow viewpoint.

Conclusion

"The great thing about this world is not so much where we are but where we are going," stated Oliver Wendell Holmes.

Years ago, physicians worried about identifying disease processes and seeing their patients quietly and as comfortably as possible through the end of the natural process. We have responded to the scientific findings that allow us mastery over our own environment and improved patient care. We now find ourselves with new problems that are somewhat of our own making from our past successes. We all have shared in medicine's excellence and in creating better quality in medical practice for our patients. Now, with a clear awareness of change and adaptation as a way of life, we have great responsibility to look beyond 1985 to longer-term goals that will allow future generations access to the Golden Thread.

All of us in this organization are dedicated to the continuous spinning of our Golden Thread—high-quality care in obstetrics and gynecology. Over the years we all have been leaders in adapting to the pressures for change and are in positions—locally, statewide, and nationally—to ensure that these changes follow and strengthen our Golden Thread. Lest we feel that the pressures of change are peculiar to us in this age, let me end with a quote from an Italian statesman who urged his countrymen to change and to adapt to their times and not rely on past glories. In 1513 Machiavelli wrote in *The Prince*, "It must be remembered that there

is nothing more difficult to plan, more doubtful of success, nor more dangerous to manage than the creation of a new system. For the initiation has the enmity of all who would profit by the preservation of the old institution and merely lukewarm defenders in those who would gain by the new one."

Peritoneal fluid in patients with and without endometriosis: Prostanoids and macrophages and their effect on the spermatozoa penetration assay

K. J. Chacho, M.D., M. Stronkowski Chacho, M.D., P. J. Andresen, B.S., and A. Scommegna, M.D.

Chicago, Illinois

Peritoneal fluid from 35 women with endometriosis and from 34 control women was aspirated at laparoscopy and analyzed. No differences in prostanoid levels were found. The peritoneal fluid volume, macrophage concentration, macrophage content, and content of activated macrophages as measured by acid phosphatase staining were all significantly elevated in the endometriosis patients. The macrophages were incubated and the medium was added to the zona-free hamster egg sperm penetration assay. This medium caused a significant decrease in the percentage of ova penetrated in this assay. It is postulated that one of the mechanisms of infertility in women with endometriosis may involve the increased number of activated macrophages and their ability to interfere with sperm-egg interaction. (AM J OBSTET GYNECOL 1986;154:1290-9.)

Key words: Peritoneal fluid, endometriosis, macrophages

It is generally accepted that women with endometriosis are less fertile. In advanced disease tubal occlusion and/or peritubal adhesions caused by endometriosis may interfere mechanically with ovulation, ovum pick-up, and ovum transport. However, in mild endometriosis the mechanisms responsible for infertility are not known.

Drake et al.[1] found that patients with endometriosis had significantly greater amounts of peritoneal fluid compared with those of disease-free women. They also showed that the peritoneal fluid of patients with mild endometriosis contained significantly higher levels of thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$ when compared with the fluid obtained from patients without evidence of the disease. These substances are stable metabolites of thromboxane A_2 and prostacyclin, respectively. They postulate that these products or their precursors could act on smooth muscle and interfere with tubal function. This would explain a mechanism by which mild endometriosis causes infertility. They suggested that mild endometriosis associated with infertility could be treated by regulation of prostaglandin synthetase activity.

Rock et al.[2] found that endometriosis was not associated with an increase in peritoneal fluid volume. They also analyzed the peritoneal fluid concentrations of several prostanoids in women with endometriosis and in women without evidence of the disease. They found

that the levels of prostaglandin E_2, prostaglandin $F_{2\alpha}$, 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$ (a stable product of prostaglandin $F_{2\alpha}$), and thromboxane B_2 were not significantly different in the two groups when measured during the proliferative phase of the cycle. These results were confirmed by Sgarlata et al.[3] and by Dawood et al.[4] Interestingly however, in a more recent paper, Badawy et al.[5] reported a significant difference in the levels of prostaglandin $F_{2\alpha}$ and prostaglandin E_2 in the peritoneal fluid in these two groups of patients.

Haney et al.[6] have found increased peritoneal fluid volume and increased numbers of macrophages in the peritoneal fluid of patients with infertility and endometriosis when compared with those of both fertile women and infertile women without endometriosis. They speculated that these inflammatory cells may act as antifertility effector leukocytes in the microenvironment within the pelvic cavity. Similar cell-mediated effects have been demonstrated in individuals wearing intrauterine contraceptive devices.[7] Additional work from their laboratory[8] has indicated that phagocytosis of sperm by these macrophages may indeed be a mechanism of infertility in patients with endometriosis.

Halme et al.[9] have found that mild endometriosis is associated with activation of pelvic macrophages as measured by acid phosphatase staining. They suggested that this might be a factor in the associated infertility since these activated macrophages could either phagocytose gametes or release active compounds into the surrounding fluid. They did not find a difference in prostaglandin E_2 or $F_{2\alpha}$ content or in macrophage concentration of the peritoneal fluid.

Halme and Hall[10] have shown that peritoneal fluid from patients with endometriosis did not affect human sperm penetration of zona-free hamster ova. In their study, however, all cells were removed from the fluid before it was tested, and the fluid was heat inactivated.

The purpose of this study is fourfold: (1) to compare the peritoneal fluid volume and prostanoid content in patients with endometriosis with those in women without the disease, (2) to measure macrophage concentration and macrophage activation in patients with and without endometriosis, (3) to determine if peritoneal macrophages release active substances capable of affecting sperm penetrating capacity, and (4) to investigate the possibility of altering these peritoneal fluid constituents by administering ibuprofen, a nonsteroidal antiprostaglandin agent.

Material and methods

Peritoneal fluid was aspirated from 69 women undergoing laparoscopy for evaluation of infertility or for elective sterilization. Thirty-five women were found to have endometriosis. Of these, two had Stage III disease, eight had Stage II, and the remainder had Stage I endometriosis, according to the American Fertility Society classification. Thirty-four women were disease free. Of this latter group nine women received 400 mg of ibuprofen four times a day for 3 days immediately before laparoscopy. The final dose was given at midnight before the procedure. This regimen is effective for treatment of dysmenorrhea.[11] Four of the women with endometriosis received ibuprofen.

At laparoscopy all peritoneal fluid was removed from the anterior and posterior cul-de-sac with a multiport aspirating cannula. The volume was recorded and the fluid was immediately placed into 15 ml polystyrene centrifuge tubes containing 100 U of heparin and transported on ice to the laboratory. The day of the menstrual cycle was recorded. Endometrial biopsy was also used to confirm ovulation.

An aliquot of the fluid was centrifuged at 800 × g for 10 minutes. The supernatant was frozen at −80° C and stored for future analysis for thromboxane B_2, 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$, 6-keto-prostaglandin $F_{1\alpha}$, and prostaglandin E.

Three milliliters of the remaining fluid was diluted 1 : 1 with cold phosphate-buffered saline, gently layered over 3 ml of ficoll-diatrizoate in a polystyrene centrifuge tube, and centrifuged at 420 × g for 30 minutes. The interphase cells were then centrifuged at 400 × g for 10 minutes at 4° C and the pellet was resuspended in 3 ml of freshly prepared Biggers, Whitten, and Wittingham (BWW) medium containing 3 mg of human serum albumin per milliliter. This same batch of medium was to be used for the spermatozoa penetration assay the next day. The cells were then counted in a hemacytometer.

An additional milliliter of the modified BWW medium was added and the cells were washed by mixing. The specimen was then centrifuged at 200 × g for 10 minutes at 4° C. The supernatant was discarded and the pellet was resuspended in the modified BWW media to a concentration of 1.5×10^6 cells per milliliter.

One milliliter of this suspension was then placed into a 35 mm plastic culture dish and incubated overnight at 37° C. Studies with the use of 0.4% trypan blue dye revealed no significant difference in cell viability before and after the incubation period.

The remaining suspension was diluted to 0.4×10^6 cells per milliliter. With a pasteur pipette, four drops of this suspension was placed into each of four chambers of a cytocentrifuge and cytospin slides were prepared. Two slides were stained with Giemsa stain and used to determine the percentage of macrophages. Haney et al.[6] have shown that this technique gives results within 5% of those obtained with nonspecific esterase staining. The two remaining slides were stained for acid

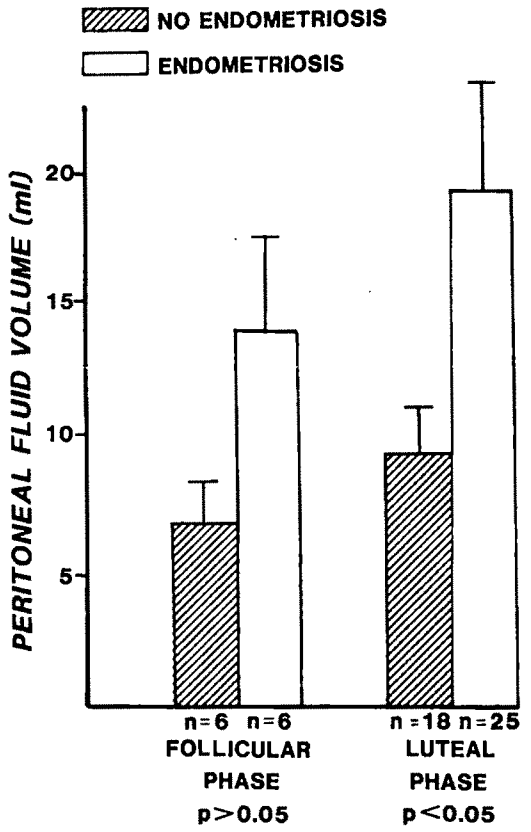

Fig. 1. Peritoneal fluid volume. *Open bars* indicate mean volume in endometriosis patients. *Hatched bars* indicate mean volume in patients without endometriosis. *Vertical lines* indicate SEM.

phosphatase activity by the method of Burstone[12] to determine macrophage activity. One thousand cells were counted for each patient.

After the overnight incubation the medium containing the macrophages was centrifuged at 800 × g for 10 minutes. It was then added to the spermatozoa penetration assay to determine if the supernatant contained any active substances that were released or secreted by the macrophages that were capable of affecting sperm penetration.

The spermatozoa penetration assay technique used in our laboratory[13] is a modification of that of Rogers et al.[14] Briefly, 0.5 × 10^6 motile spermatozoa from a donor were added to two separate insemination drops. One control drop contained 200 μl of modified BWW media and the other contained 160 μl of this medium plus 40 μl of the modified BWW medium preincubated for 18 hours with macrophages. Zona-free hamster eggs were then added to each drop and allowed to incubate for 3 hours.

Slides were made by a standard squash technique on paraffin-prepared slides. These were then "quick fixed" in glutaraldehyde and allowed to fix overnight in formalin. Fixed slides were dehydrated in ethanol, stained with acetolacmoid, and scored for penetrations under a phase-contrast microscope (40 × dry objective). The percentage of penetration (number of ova penetrated per number of ova) and the penetration index (number of spermatozoa penetrating ova per number of ova penetrated) were both determined.

Table I. Peritoneal fluid prostanoids in women with and without endometriosis

	Endometriosis (n = 5)	*No endometriosis (n = 5)*	*p*
Concentration (ng/ml)			
TxB_2	0.068 ± 0.019	0.051 ± 0.009	NS
PGFM	0.407 ± 0.188	0.237 ± 0.020	NS
6-Keto-$PGF_{1\alpha}$	0.442 ± 0.117	0.340 ± 0.009	NS
PGE	0.552 ± 0.086	0.588 ± 0.018	NS
Total content (ng)			
TxB_2	1.48 ± 0.55	0.84 ± 0.13	NS
PGFM	6.63 ± 1.95	3.66 ± 0.66	NS
6-Keto-$PGF_{1\alpha}$	9.78 ± 3.43	5.03 ± 0.72	NS
PGE	8.57 ± 1.05	11.11 ± 2.47	NS

Values are mean ± SEM. TxB_2 = Thromboxane B_2; PGFM = 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$; 6-keto-$PGF_{1\alpha}$ = 6-keto-prostaglandin $F_{1\alpha}$; PGE = prostaglandin E.

Prostanoids were determined by radioimmunoassay. The technique has been described.[15] Briefly it consisted of solvent extraction, purification on a silicic acid chromatography column, and radioimmunoassay with the use of antibodies raised against the prostanoids of interest.*

The two-tailed *t* test and multiple analysis of variance were used for statistical evaluation where appropriate.

Results

The results of the peritoneal fluid volume analysis are seen in Fig. 1. In the follicular phase of the cycle

*The 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$ antiserum (560-JCC-140D, The Upjohn Co., Kalamazoo, Michigan) did cross react with the prostaglandins as follows: 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$, 100%; 15-keto-prostaglandin $F_{2\alpha}$, 20%; and the C16 metabolite of prostaglandin $F_{2\alpha}$, 13,14-dihydro-prostaglandin $F_{2\alpha}$, and prostaglandin $F_{2\alpha}$, <1%. Cross-reactivity for the thromboxane B_2 antiserum (SG1003, Seragen, Boston, Massachusetts) was: thromboxane B_2, 100%; prostaglandin E_1, E_2, $F_{1\alpha}$, $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$, <0.1%. Prostaglandin E antiserum (1001, Seragen) cross-reactivity was: prostaglandin E_1, 100%; prostaglandin E_2, 100%; prostaglandin A_1, 3%; prostaglandin A_2, 6%; 6-keto-prostaglandin E_1, 1%; prostaglandin $F_{2\alpha}$, 1.3%; prostaglandin $F_{1\alpha}$, 1%; 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2, <1%. Cross-reactivity for the 6-keto-prostaglandin $F_{1\alpha}$ antiserum (SG 1004, Seragen) was as follows: 6-keto-prostaglandin $F_{1\alpha}$, 100%; prostaglandin $F_{1\alpha}$, 7.8%; 6-keto-prostaglandin E_1, 6.8%; prostaglandin $F_{2\alpha}$, 2.2%; prostaglandin E_1, 0.7%; prostaglandin E_2, 0.6%; thromboxane B_2, 15-keto-prostaglandin $F_{2\alpha}$, and 15-keto-prostaglandin E_2, <0.01%.

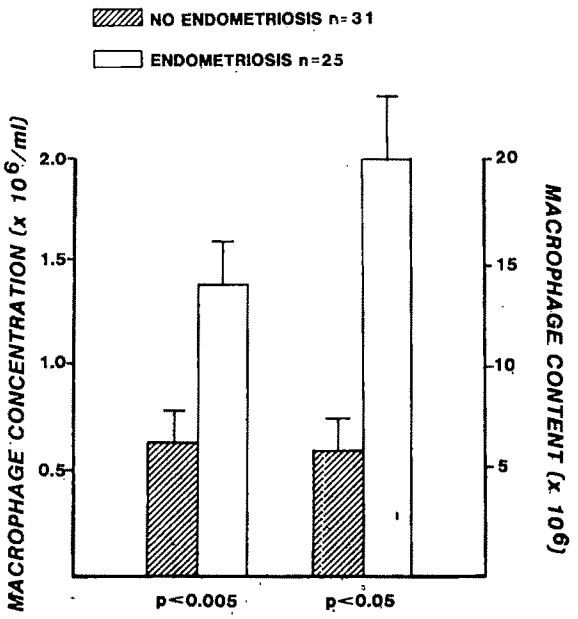

Fig. 2. Mean peritoneal fluid macrophage concentration and content in endometriosis patients *(open bars)* and patients without endometriosis *(hatched bars)*. *Vertical lines* indicate SEM.

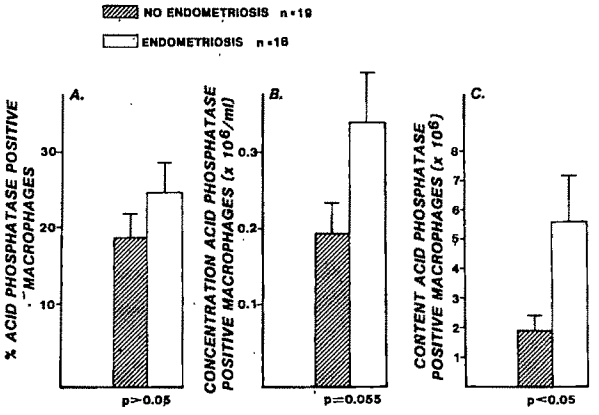

Fig. 3. Mean peritoneal fluid acid phosphatase–positive macrophage percentage *(A)*, concentration *(B)*, and content *(C)*. *Open bars* indicate values in endometriosis patients. *Hatched bars* indicate values in patients without endometriosis. *Vertical lines* indicate SEM.

the peritoneal fluid volume in milliliters found in the pelvic cavity of women with endometriosis, 13.8 ± 3.6 (mean + SEM), was larger than but not significantly different from that obtained from disease-free women, 6.7 ± 1.4. In the luteal phase, however, a significantly larger volume of peritoneal fluid was found in women with endometriosis, 19.2 ± 4.0 ml, than in women without this disease, 9.3 ± 1.5 ml ($p < 0.05$). Ibuprofen had no significant effect on peritoneal fluid volume.

Cul-de-sac prostanoids (15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$, thromboxane B_2, 6-keto-prostaglandin $F_{1\alpha}$, and PGE) in women with endometriosis were not significantly different from those of the control group. This remained true for both prostanoid concentration and total content (Table I). During the course of this study other investigators[3, 4, 9] confirmed these results, which were consistent with the earlier report of Rock et al.[2] Because of this information, in combination with our further findings that neither ibuprofen nor phase of the menstrual cycle affected prostanoid levels in women without endometriosis, we elected to divert our efforts toward analysis of peritoneal fluid macrophages.

Women without endometriosis had a significantly lower concentration of macrophages in the peritoneal fluid (0.65 ± 0.10 × 10^6 cells per milliliter, mean ± SEM) when compared with that of women with this disease (1.39 ± 0.20 × 10^6 cells per milliliter, $p < 0.005$). The total macrophage content of the peritoneal fluid in patients without endometriosis was 5.75 ± 1.39 × 10^6 cells (mean ± SEM), which was also significantly lower than 19.88 ± 3.31 × 10^6 cells, found in women with endometriosis ($p < 0.01$) (Fig. 2).

The phase of the menstrual cycle was found to affect the macrophage concentration. Women in the follicular phase (not including the menstrual phase) had a mean macrophage concentration (±SEM) of 1.64 ± 0.20 × 10^6 cells per milliliter, higher than 0.87 ± 0.11 × 10^6 cells per milliliter found in luteal phase fluid (0.006 = $p < 0.01$). Ibuprofen did not affect macrophage concentration or content.

The mean percentage (±SEM) of positive macrophages for acid phosphatase in the peritoneal fluid of women without endometriosis was 18.26 ± 3.39 (Fig. 3). This value was higher in the peritoneal fluid of endometriosis patients (24.54% ± 3.90%); however, the difference was not significant.

The mean concentration (±SEM) of acid phosphatase–positive macrophages in the peritoneal fluid of women without endometriosis (Fig. 3) was lower (0.19 ± 0.04 × 10^6 cells per milliliter) than in patients with endometriosis (0.34 ± 0.07 × 10^6 cells per milliliter). In this case the difference approached significance ($p = 0.055$) (Fig. 3).

Finally, the number of acid phosphatase–positive macrophages in the peritoneal fluid of women without endometriosis (1.89 ± 0.57 × 10^6, mean ± SEM), as seen in Fig. 3, was significantly lower than the number found in endometriosis patients (5.64 ± 1.60 × 10^6, $p < 0.05$).

Neither the phase of the menstrual cycle nor the administration of ibuprofen had a significant effect on activated macrophages as measured by acid phosphatase staining.

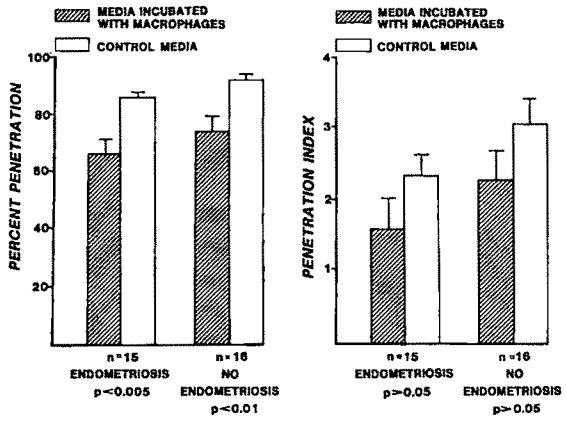

Fig. 4. Mean percentage of penetration obtained with medium incubated with peritoneal macrophages from patients with and without endometriosis. *Open bars* indicate control values. *Hatched bars* indicate patient values. *Vertical lines* indicate SEM.

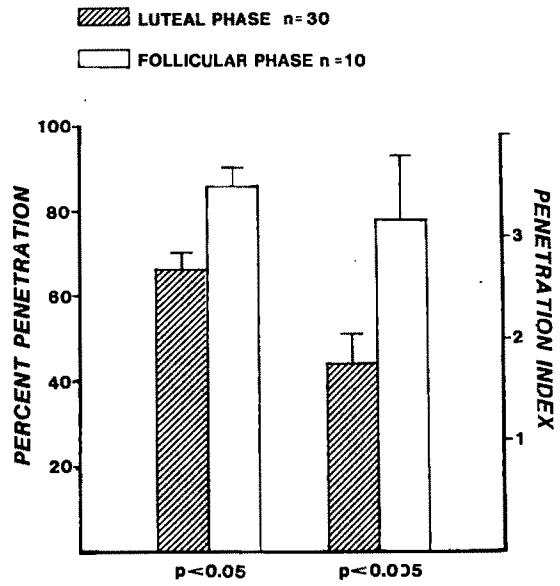

Fig. 5. Mean percentage of penetration and penetration index obtained with medium incubated with peritoneal macrophages obtained during either the luteal *(hatched bars)* or follicular *(open bars)* phase of the menstrual cycle. *Vertical lines* indicate SEM.

Medium in which peritoneal macrophages had incubated was found to have a significant effect on the number of ova penetrated in the spermatozoa penetration assay in both endometriosis patients and women without the disease (Fig. 4). The mean percentage of penetration (±SEM) in assays where the medium had been incubated with peritoneal fluid macrophages from endometriosis patients was 66.33 ± 5.94 whereas control medium produced a mean (±SEM) percentage of penetration of 85.66 ± 2.17 ($p < 0.005$) in the same assays. Medium that had incubated with macrophages from patients without endometriosis resulted in a mean (±SEM) percentage of penetration of 73.31 ± 5.98. Control medium in these assays produced a value of 92.12 ± 2.12 ($p < 0.01$).

Although medium that had incubated with peritoneal macrophages had a tendency to lower the mean (±SEM) penetration index both in endometriosis patients (1.59 ± 0.45 versus 2.31 ± 0.33 for control women) and in disease-free women (2.27 ± 0.40 versus 3.06 ± 0.035 for control women), this difference was not significant.

The phase of the menstrual cycle was found to have a significant effect on the percentage of penetration and apparently on penetration index (Fig. 5). The mean percentage of penetration (±SEM) produced by medium that was incubated with peritoneal macrophages recovered during the follicular phase of the cycle was 85.00 ± 4.78, which was significantly higher than that resulting from medium that had been incubated with peritoneal macrophages aspirated during the luteal phase, 65.60 ± 3.94 ($p < 0.05$). The mean penetration index (±SEM) produced by follicular macrophage–incubated medium was 3.09 ± 0.66, whereas the corresponding result for luteal macrophage medium was 1.71 ± 0.27 ($p < 0.005$).

The penetration index was also apparently significantly affected by ibuprofen. The mean penetration index produced by medium that had been incubated with peritnoneal macrophages recovered from women who received ibuprofen was significantly higher than that seen with medium that had been incubated with peritoneal macrophages from women who did not receive this nonsteroidal anti-inflammatory agent ($p < 0.05$). However, a two-way interaction between ibuprofen status and phase of the menstrual cycle approaching significance ($p = 0.051$) was found for the penetration index variable, indicating that the apparent effects of ibuprofen and phase of the menstrual cycle on penetration index may be the result of confounding variables.

With the use of discriminant analysis a mathematical model was developed in an attempt to predict which patients would have endometriosis on the basis of the results of selected variables. The variable selected by the model to be most predictive of endometriosis was the macrophage concentration followed by the number of acid phosphatase–positive cells, and the macrophage number in that order. Twenty-four patients without endometriosis and 21 patients with this disease had the necessary data to be entered into the model. Of the former group 22 patients (91.7%) were correctly predicted to be endometriosis free whereas two patients (8.3%) were predicted to have the disease. Of the patients with endometriosis 13 (61.9%) were correctly predicted to have the disease by this model whereas eight

patients (38.1%) were predicted to be disease free. Overall 77.78% of cases were correctly classified by this mathematical model.

Comment

We have found no difference in the peritoneal fluid volume between women with and without endometriosis in the follicular phase of the menstrual cycle. In the luteal phase, however, women with endometriosis had a significantly larger volume of peritoneal fluid. When these two groups were combined the difference remained significant. These findings are consistent with those of Drake et al.[1] and Haney et al.[6] (increased peritoneal fluid volume in endometriosis patients) and with those of Rock et al.[2] (no difference in peritoneal fluid volume in the follicular phase).

Our prostanoid data are consistent with those of Rock et al.,[2] Sgarlata et al.,[3] and Dawood et al.,[4] indicating that peritoneal fluid prostanoids are probably not elevated in women with endometriosis. The finding that prostanoid levels, in our study and others,[2-4] were much lower than those reported by Drake et al.[1] and by Badawy et al.[5] suggests that substances other than the specific prostanoid may have been measured.

The increased level of macrophages found in the peritoneal fluid of women with endometriosis suggests that such macrophages may play a role in the infertility of these patients. The increased number of activated macrophages in patients with endometriosis, consistent with the data of Halme et al.,[9] also is supportive of such a concept.

These macrophages may phagocytose sperm as demonstrated by Muscato et al.[8]

Macrophages may also release substances into the pelvic environment that can inhibit sperm-egg interaction.

We have found that medium incubated with peritoneal macrophages caused a significant decrease in the number of zona-free hamster eggs penetrated by sperm in our spermatozoa penetration assay. Macrophages from endometriosis patients, however, were no more effective at decreasing the percentage of penetration than macrophages from disease-free women. Thus, if macrophages play a role in the infertility of women with endometriosis, they do so because of their increased number, not because of any particular property of the macrophages found in women with endometriosis. In our experimental design, macrophages from endometriosis patients as well as from disease-free women were brought to the same concentration before incubation. Our spermatozoa penetration assay results therefore do not reflect the larger concentration of macrophages found in endometriosis patients. Macrophages may release substances into the pelvic environment that are capable of decreasing sperm penetration; infertility in endometriosis patients may be due in part to the larger number of macrophages in these women. These substances, as yet undetermined, are heat labile since heat-inactivated peritoneal fluid has no effect on the penetration of hamster ova by sperm.[10] Additional studies are currently being undertaken in our laboratory to further characterize this effect.

Why medium incubated with macrophages obtained during the luteal phase was more effective in decreasing sperm penetration parameters than that incubated with macrophages from the follicular phase is unclear. A similar study performed in the periovulatory period would have more clinical relevance.

At the onset of the study we postulated that peritoneal fluid prostanoids and macrophages might be causally related to the infertility in endometriosis. We therefore evaluated the ability of ibuprofen (a prostaglandin synthetase inhibitor and nonsteroidal anti-inflammatory agent) to alter prostaglandins or inflammatory cells in the peritoneal fluid.

Surprisingly the only parameter among those evaluated significantly affected by ibuprofen was the penetration index. Ibuprofen seemed to lessen the ability of macrophages to release factors that decrease sperm penetration. The number of patients who received ibuprofen and were found to have endometriosis, however, was small ($n = 4$) and further work is needed to confirm this finding. If the finding is confirmed, a therapeutic role for ibuprofen in endometriosis-related infertility may be considered.

The inability of ibuprofen to affect peritoneal fluid prostaglandin levels and other macrophage parameters in our study may be due to the dosage schedule. The dosage used is effective in treating dysmenorrhea, indicating its effect on endometrial prostaglandins. However, Jones et al.[16] have demonstrated that prostaglandin content of some tissues can be affected more readily than others by antiprostaglandin administration. In peritoneal fluid of the rabbit, prostaglandin values are relatively insensitive to indomethacin administration when compared with kidney or blastocyst prostaglandin values.

The development of a mathematical model to predict endometriosis could potentially become a tool in anticipating which patients may have disease that is not evident at the time of laparoscopy. Although the number is small, follow-up of the women who were predicted by the model to have endometriosis, yet who had no visible disease at the time of laparoscopy, should prove interesting. If these women are found to develop endometriosis, our model may prove to be a valuable instrument to determine which patients may have latent or occult disease.

In conclusion, we have demonstrated that patients with endometriosis have more peritoneal fluid that con-

tains more macrophages when compared with fluid in women without this disease. Endometriosis patients also have a larger number of activated macrophages in the peritoneal fluid. In addition these macrophages appear to be releasing compounds that are capable of decreasing sperm penetration. Whether ibuprofen may be able to reverse this phenomenon is not clear.

We gratefully acknowledge the assistance of Dr. Marija Norusis in performing the statistical analysis, and the technical assistance of Ms. Hsui Tseng and Mr. Dot Chin. We also thank the Clinical Cytology Department at Michael Reese Hospital for allowing us to use their facilities.

Discussion

Dr. Hassan Amirikia, Detroit, Michigan. The association of endometriosis and infertility is well known[1]; however, the exact mechanisms involved remain unclear and are as controversial as the etiology of the endometriosis. In addition, even when women with endometriosis do conceive, recent studies indicate a significant increase in the incidence of first trimester spontaneous abortions in untreated patients.[2]

To identify the factor(s) involved in the pathophysiology of infertility related to endometriosis, many studies have been performed during the last decade. Their authors have concluded that peritoneal changes in endometriosis may lead to infertility in a variety of ways: (1) Increased peritoneal fluid prostaglandins may cause tuboovarian or uterine dysfunction and interfere with fertilization and/or implantation. (2) Luteinization may occur without ovluation. Donnez et al.[3] observed fewer ovulation ostia in ovaries of patients with endometriosis compared with those in normal ovulatory women and ostia that were comparable with those of patients with the luteinized unruptured follicle syndrome. (3) The increased number and activity of the peritoneal fluid macrophages may interfere with fertilization by an increase in phospholipases, which act on cell membrane phospholipids to produce arachnoid acid used in the synthesis of prostaglandin at the site of the reaction,[4] or by an increase in phagocytosis of the spermatozoa.[5]

Dr. Chacho and associates, in their study, concluded that patients with endometriosis have more peritoneal fluid that contains increased macrophages. Although the concentration and percentage of active macrophages were not different, patients with endometriosis have a larger number of activated macrophages compared with those in normal women. In addition, they proposed a very interesting concept that the macrophages may be releasing compounds that could interfere with fertilization as demonstrated by decreasing sperm penetration into hamster eggs. Ibuprofen seemed to lessen the ability of macrophages to release this factor although the number of women receiving this antiprostaglandin agent was small. This is a very interesting study and we hope the authors pursue their work further to identify this factor, which could help us to understand the exact mechanism of endometriosis and also, in the future, direct us to develop a new method of contraception.

There are, however, some questions about this study. Dr. Chacho and associates have reviewed 69 patients who underwent laparoscopic procedures for infertility

or sterilization. They found 35 patients with endometriosis and 34 without. It is not clear how many of these 35 patients with endometriosis were fertile and had just had the laparoscopic procedures for the purpose of sterilization; what were their findings in the peritoneal fluid in this group of patients? The authors state that the amount of peritoneal fluid was higher in the luteal phase than in the follicular phase, yet only six women in each group were studied during the follicular phase; 18 of 25 were in the luteal phase. Is six cases a large enough sample to be entirely confident of this statement? In both follicular and luteal phases, the mean peritoneal fluid volume of women with endometriosis was twice that of those without endometriosis. If the number of women in the follicular phase were greater, both probably would have been significant. Prostanoid concentrations are reported for only five of 35 in the first group and five of 34 in the second group of women; how do the authors know that these five are representative of the other 30 and 29 women? If they had done more measurements, they might have seen different results. In addition, the collection of samples and the performance of radioimmunoassays for prostanoids are fraught with potential problems.[6] Are the authors certain that their methods have overcome these problems? They cite a 1985 article as validation. In order to study macrophage secretions, macrophages were incubated overnight with medium and cell viability was checked the next day by trypan blue exclusion. However, in the presence of the exogenous protein (human serum albumin) this method can give inaccurately high values.[7] If the macrophages were dying, they could have released factors not normally present in intraperitoneal fluid that could reduce the percentage of penetration of sperm into the hamster egg. These factors may not represent normal cell function. The authors should have examined cell viability by another method, such as phase contrast refraction.

These authors have constructed a model from their data and then applied it to their data. The fact that they obtained a 77.8% correct classification is surprising; it should have been closer to 100% if the model were properly constructed. They need to use the model on another group of women to test its "goodness of fit."

The critiques regarding sample size applied to Fig. 1 presented by the authors also can be applied to Fig. 5 (percentage of penetration and penetration index). The number of follicular phase samples was one third that of the luteal phase. With higher numbers, the significance level could be different.

Although there were 35 and 34 subjects in Groups 1 and 2, respectively, the highest numbers in the figures are 25 and 31. There is a lack of data for some parts of this study, and if data from the whole group are not reported, how can one say the population with endometriosis is properly represented? This is a promising pilot study if the methodologic questions raised can be answered adequately.

DR. L. RUSSELL MALINAK, Houston, Texas. Dr. Chacho and colleagues have undertaken an extensive research project directed at the answer to one of the most elusive problems in gynecology, namely, the etiology of infertility in endometriosis patients when anatomic distortion of the internal genitalia has not occurred.

There are several questions that must be clarified.

First, regarding patient selection, it is stated that laparoscopy was performed for evaluation of infertility and for elective sterilization and that 35 patients had endometriosis and 34 were disease free. It is not stated, however, how many patients in each group had endometriosis, a fact important in interpreting these data. We have all seen endometriosis at the time of laparoscopy for tubal sterilization; such a finding, if present or not observed at laparoscopy for tubal sterilization, would bias the control group. Also, findings such as pelvic adhesions, leiomyomas, or other pelvic abnormalities that might alter peritoneal fluid and macrophage physiology are not mentioned in either group. Patient demographics and operative findings are thus incomplete. For example, if some patients in the sterilization group had intrauterine contraceptive devices in situ at the time of the laparoscopic procedure, macrophage changes might be observed, which circumstance would eliminate that patient as a control.

Regarding study design, it is of concern that the authors studied peritoneal fluid only in the proliferative phase and the luteal phase. The dynamism of each phase of the cycle demands that biochemical and cell population studies be evaluated at several times during each phase. Contrast in your mind's eye the observable differences of peritoneal fluid at laparoscopy performed on cycle day 5 versus day 14. To emphasize this concern, Halme et al.,[1] in 1984, published results

that suggested "that female peritoneal macrophages are continuously responding to stimuli."

The authors do not provide clear information about the concentration of peritoneal fluid that was studied. It is known that high concentrations of peritoneal fluid are toxic to gametes and embryos. Thus a major question must be raised: Were the observed differences in the sperm penetration assay secondary to a specific effect on sperm function or were they secondary to a nonspecific toxic effect on sperm, perhaps as demonstrated by altered sperm motility?

Based on these considerations, how did the authors determine the concentration of peritoneal fluid and were observations of sperm motility made?

Since it has been previously demonstrated in endometriosis patients that peritoneal macrophages are morphologically different and exhibit different biologic behavior compared with those in nonendometriosis control patients, research to clarify specific mechanisms is of paramount importance. Based on this study, it is not possible to state unequivocally that peritoneal macrophages interfere with sperm-egg interaction.

It is hoped that the authors will continue to pursue this research in a patient population with better documentation of clinical status, for, when one reviews the literature on peritoneal fluid macrophages, there is a distinct feeling that the answer to one of the most perplexing questions in medicine is near.

Dr. Chacho (Closing). Several points were made, and I will try to address the most salient ones. We designed this project as a preliminary study to look at several different aspects of peritoneal fluid in patients both with and without endometriosis. In order to obtain a significant number of samples our patients were selected from the practices of five physicians at Michael Reese Hospital and Medical Center. Most of these physicians tended to perform laparoscopy in their patients during the luteal phase of the cycle; therefore there was a considerable difference in the number of samples obtained in the luteal phase compared with the number in the follicular phase. We had no control over the time these physicians brought their patients into the hospital for operation.

Similarly, only a small number of these patients were actually to undergo tubal sterilization. The majority were infertile.

We do have the data as to which patients with endometriosis were infertile and which were fertile. We have not looked at that portion of the data yet.

With respect to several of the other comments concerning some of the problems that are evident in this work, I reemphasize that this was a preliminary study. We are undertaking additional studies at this time with patient groups that are more controlled. We are also looking at the possibility of a problem with cell viability. In the present study we did find that before and after incubation there was no significant difference in the number of viable cells. However, as some of the commenters mentioned, the effects being observed could be those of toxic substances. We are currently looking at cells that have been heat-killed to see if they release into the media anything that might affect sperm penetration.

Prostanoids were assayed in only five patients with endometriosis and in five disease-free women. This was a result of the findings that appeared in the literature during the course of our study. The papers by Sgarlata et al. and Dawood et al. were not in the literature when we began to organize this research. Dr. Sgarlata's paper appeared in 1983, and I first heard Dr Dawood present his work the same year. Since both of these authors confirmed the work of Rock et al. and since our preliminary data also indicated that there was no difference in prostanoid levels between endometriosis patients and women without this disease, we decided not to pursue the prostaglandin analysis. The antisera are extremely expensive, and we did not think it prudent to continue to look at prostaglandin levels when other investigators also had found no elevation in endometriosis patients. We decided to concentrate our efforts on the macrophage studies.

The model discussed in the paper was a benefit of the statistical analysis. The statistician had developed, with the use of discriminate analysis, a model by which we might be able to predict which patients had endometriosis and which patients did not, based on several findings. The particular finding that the model predicted to be most significant was the macrophage concentration. It also predicted that the macrophage content, the concentration of activated macrophages, and the total content of activated macrophages would be significant, and using these particular criteria we made the predictions.

Obviously this appears to be circular reasoning. If you take a group of patients and make a model and then use the model to evaluate that same group of patients you might expect the result to be 100%. However, statistically there is value in such a model. We have not placed too much emphasis on the model at this time since it has not been tested prospectively. There were two patients that the model predicted should have endometriosis, and yet none was seen. To date neither of them has shown any sign of developing endometriosis. We will continue to follow up these patients and are planning to look at other women prospectively. The question was asked as to whether a thorough diagnostic laparoscopy was performed. In most cases I was present in the operating room during the laparoscopy and was able to examine the pelvis. In general the majority of our patients were infertile and consequently a thoroughly diagnostic laparoscopy was performed by the primary physician. We did make a special point of

doing a thorough diagnostic laparoscopy in those patients who were having tubal sterilization. We did not accept any patients who were using steroids or intrauterine contraceptive devices for contraception. All of the patients were using various barrier methods of contraception before the tubal ligation.

A question was asked about the concentration of peritoneal fluid. From this I assume the question concerned the concentration of peritoneal fluid used in our various assays. We obtained 3 ml of peritoneal fluid, isolated the macrophages with the use of ficoll-diatrizoate, and then determined the concentration of macrophages in that particular fluid. We brought those macrophages to a concentration of 1.5×10^6 cells per milliliter in fresh medium. We did not put them back in the peritoneal fluid. Therefore, the peritoneal fluid itself, unless it was closely adherent to the macrophages, should not have been present in our incubates nor should it have been able to affect the penetration as measured by our sperm penetration assay.

Conservative treatment of ectopic pregnancy with methotrexate

Steven J. Ory, M.D., Alelei L. Villanueva, M.D., Peter K. Sand, M.D., and Ralph K. Tamura, M.D.

Chicago, Illinois

Six subjects with distal ampullary ectopic pregnancies were treated with four doses of intravenous methotrexate (1.0 mg/kg) followed by four doses of leucovorin (0.1 mg/kg, intramuscularly). The diagnosis was established in all cases by laparoscopy following sonography and radioimmunoassay for serum β subunit of human chorionic gonadotropin. Subjects were followed with daily quantitative serum β-human chorionic gonadotropin radioimmunoassay and sonography. Five of the six subjects experienced resolution of their ectopic pregnancy without additional surgical treatment. One subject underwent salpingectomy following treatment. Morbidity also included three patients with mild stomatitis or gastritis, and two patients had transient elevations of serum transaminase levels. Two patients had protracted courses and received blood transfusions. The most abrupt response and most uncomplicated courses were experienced in the three subjects with initial human chorionic gonadotropin levels below 1000 mIU/ml. This preliminary experience suggests that methotrexate may be an effective alternative for the treatment of early ectopic pregnancy. (Am J Obstet Gynecol 1986;154:1299-1306.)

Key words: Ectopic pregnancy, methotrexate, infertility

The incidence of ectopic pregnancy in the United States increased threefold during the 1970s with over 52,000 cases reported during 1980.[1] During this same interval the death-to-case ratio declined from 3.5 to 0.9; only 39 deaths occurred in the United States in 1979. The reasons for this dramatic increase in incidence have not been fully elucidated, but the prevalence of pelvic inflammatory disease and the possible contribution of intrauterine device use have been cited as contributing factors. The availability and liberal use of sensitive and specific radioimmunoassays for β subunit of human chorionic gonadotropin (β-hCG), high-resolution sonography, and laparoscopy have permitted earlier and more frequent diagnosis and have resulted in a significantly reduced mortality rate.

Despite this apparent success in diagnosis and treatment, fertility remains impaired. Term pregnancy following ectopic pregnancy occurs in only 30% of patients traditionally treated with salpingectomy.[2-4] This observation has led to the development of a variety of surgical techniques including linear salpingotomy, segmental resection and reanastomosis, and tubal abortion to conserve the oviduct and future fertility potential. Those procedures utilizing microsurgical techniques have resulted in slightly improved fertility, with investigators reporting success rates ranging from 40% to 72%.[5-7]

These observations make conservative nonsurgical

therapy appealing. Such an approach would spare patients laparotomy and a conservative tubal operation and might result in less tissue trauma and subsequent adhesion formation if the ectopic pregnancy could be induced to resolve spontaneously. Ultimately, reproductive function might be less adversely affected.

Recently a case report appeared describing the successful use of methotrexate in the treatment of an interstitial pregnancy.[8] This approach was applied in the present study to determine the effectiveness and safety of methotrexate therapy in the treatment of tubal ectopic pregnancy in a series of patients.

Material and methods

Between September 1, 1984, and August 31, 1985, 52 patients presenting at Northwestern Memorial Hospital with suspected tubal ectopic pregnancies were given the option of participation in a protocol using methotrexate for treatment of ectopic pregnancy. In the sample the diagnosis of tubal ectopic pregnancy was subsequently established by β-hCG radioimmunoassay, ultrasonography, and laparoscopy. The study was explained and written informed consent was obtained before laparoscopy. An Investigational New Drug License was secured from the United States Food and Drug Administration to use methotrexate to treat tubal ectopic pregnancy before inception. The treatment protocol and consent forms were reviewed and approved by the Northwestern University and the Northwestern Memorial Hospital Institutional Review Boards and the Prentice Pavilion Research Committee.

The final decision regarding inclusion in the study was made at the time of laparoscopy. Inclusion criteria included the presence of an unruptured tubal ectopic pregnancy ≤4 cm in diameter and with <100 ml of blood in the peritoneal cavity. Photographs of the ectopic gestations were taken at laparoscopy. Subjects were excluded if they had unstable vital signs, a contraindication to laparoscopy or indications for additional abdominal surgery, a history of active hepatic or renal disease, abnormal serum blood urea nitrogen, creatinine, or transaminase levels, proteinuria, methotrexate sensitivity, active peptic ulcer disease, a white blood count of 3000, a platelet count of <10,000, or a hemoglobin of <11.0 grams of if they were deemed to be poor candidates for follow-up.

Of the original 52 patients, six subjects agreed to the protocol, signed the consent form, and satisfied the inclusion criteria. All six subjects were transferred to the Northwestern Memorial Hospital Clinical Research Center immediately after laparoscopy. All individuals were between 18 and 35 years of age, and all desired future pregnancies. The first dose of methotrexate was administered when vital signs were stable. A total of four doses of methotrexate (1 mg/kg) was given every other day. Leucovorin (citrovorum factor, 0.1 mg/kg) was given intramuscularly every other day following methotrexate administration for a total of 4 days to minimize toxicity.

Sequential Multichannel Autoanalyzer (SMA-20) determinations were repeated before each dose of methotrexate. Quantitative β-hCG radioimmunoassay, complete blood count determinations, and ultrasound studies were performed daily to evaluate response to therapy. Serum methotrexate determinations were obtained 2, 4, 24, and 36 hours after the initial dose of methotrexate. Twenty-four–hour urine collections for creatinine clearance and protein were performed the

first full day of admission and three months after therapy. A hysterosalpingogram was performed 3 months following therapy to assess tubal patency.

Patients were discharged from the Clinical Research Center when objective evidence of tubal abortion or resolution was obtained with falling hCG levels and sonographic date. They were advised to avoid subsequent pregnancy for 3 months following treatment.

Results

The patient characteristics are presented in Table I. Interestingly, five of the six subjects had a previous ectopic pregnancy. Representative hCG patterns and sonogram results are presented in Figs. 1 and 2. Fig. 3 shows the composite hCG levels of all six subjects. Five of six patients had complete resolution of their tubal pregnancies with methotrexate alone. Subjects 1, 2, and 3 had relatively rapid responses to methotrexate therapy and no significant complications (Table II). The single failure was subject 4, who developed a hemoperitoneum and acute abdomen requiring operation on therapy day 12. At operation the fallopian tube was noted to be intact and the tubal gestation was free in the peritoneal cavity; however, arterial bleeding from the tubal placental implantation site was present. There were approximately 400 ml of blood in the abdomen. The patient underwent a partial salpingectomy and had an uneventful postoperative course.

Subjects 5 and 6 had resolution of their ectopic pregnancies without laparotomy but also had complicated courses. Subject 5 had moderate abdominal pain accompanied by vaginal bleeding but remained hemodynamically stable. This episode appeared to represent a tubal abortion (judged by falling β-hCG levels, sonography, and clinical examination). One day following this episode, the patient improved dramatically, but a

2.5 gm decrease in hemoglobin since admission was still noted. She therefore received two units of packed red blood cells and plans were made to take her to the operating room. However, no further decrease in her hemoglobin and hematocrit was noted. She continued to improve clinically, and additional surgery was not performed. Subject 6 had a similar episode 24 days after beginning treatment. This prompted readmission and transfusion. She experienced rapid clinical improvement following these measures.

Other complications were minimal. Subjects 1 and 3 complained of mild stomatitis, which spontaneously resolved within 3 days of appearance. Subjects 2 and 3 had transient elevations of serum glutamic-oxaloacetic transaminase, and subject 2 also had an elevation of serum glutamic-pyruvic transaminase levels during therapy. Abrupt resolution was noted in both cases while treatment was continued. No other morbidity was observed.

Comment

Our preliminary data suggest that methotrexate may be effective in inducing tubal abortion or resorption of ectopic pregnancy; five of six subjects avoided operation. The agent appears to be most effective in pregnancies with β-hCG levels of <1,000 mIU/ml. The subjects experiencing the most complicated courses (4, 5, and 6) had significantly higher initial β-hCG levels and presumably more advanced gestations.

Conservative management was attempted in a large series of patients in Denmark in 1955.[9] In this series 68 of 119 patients (57%) with the presumptive diagnosis of ectopic pregnancy were managed without surgical intervention. In a more recent series, four of five patients with early ectopic pregnancy were successfully managed without surgery.[10] The primary problem with observant management in the Danish study was the need for prolonged hospitalization; 60% of the patients were hospitalized for over 30 days. Tanaka et al.[8] more recently described successful resolution of an interstitial ectopic pregnancy following methotrexate therapy.[8] This approach resulted in a more abrupt termination of the pregnancy, and tubal patency was preserved, as demonstrated by subsequent hysterosalpingography.

If methotrexate is used, daily quantitative β-hCG radioimmunoassay determinations appear to be a reliable parameter for following the resolution of an ectopic pregnancy. Ultrasound was also helpful when performed daily; however, ultrasound lacked the sensitivity of the β-hCG radioimmunoassay levels. It was most helpful in predicting the lack of response of subject 4. The size of the oviduct was not helpful in predicting hCG levels, since all patients had tubal pregnancies of <4 cm in diameter. The single treatment failure, subject 4, had an initial β-hCG level of 25,410 mIU/ml, and fetal heart motion was noted within the oviduct on treatment day 3. In retrospect, the subject's course might have been predicted by these findings and the delay in the decline of hCG levels (Fig. 2). Most subjects had an episode that clinically appeared to represent the tubal abortion or resorption. This event consisted of moderate abdominal pain, vaginal bleeding (in some instances with the passage of a decidual cast), and a near-linear fall in β-hCG levels following the subjective signs.

Although our results do not permit us to predict a typical hCG regression curve for resolution of a tubal pregnancy, the fall in the hCG levels of subject 3 are probably coincidental with, rather than a result of, methotrexate therapy. This subject was probably undergoing a spontaneous tubal abortion at the time of diagnosis.

What is the role of methotrexate? If a proportion of the current "epidemic" of ectopic pregnancies reflect ectopic pregnancies that in the past would have spontaneously resolved early or without sequelae or clinical detection, there may be some merit in attempting to avoid surgical intervention in these situations. Observation alone may be justifiable if hCG levels are decreasing and if the patient is clinically stable.[10] It is unlikely that methotrexate therapy will become the most common treatment for ectopic pregnancy. Our preliminary experience suggests that the agent can provide a safe and relatively effective alternative to surgery for patients with early ectopic pregnancies. Methotrexate therapy may ultimately prove to be a cost-effective alternative to surgery. We do not recommend the use of methotrexate when an ectopic pregnancy is associated with hCG levels of >10,000 mIU/ml or when fetal heart motion can be detected. Although it may be effective in more advanced tubal pregnancies, the more protracted course that we observed in those subjects makes it considerably less appealing. Considerable additional experience must be accumulated to determine safe hCG limits within which to employ therapy and to assess subsequent fertility following methotrexate treatment. If fertility in patients treated with methotrexate is significantly improved over that of surgically treated patients, its greatest potential advantage will be realized.

Discussion

Dr. G. William Bates, Jackson, Mississippi. In my opinion, when a definitive medical treatment replaces a surgical procedure, medical practice has advanced. In this paper, the authors describe the treatment of six women with early tubal ectopic pregnancies with intravenous methotrexate. Five of the six women had a complete resolution of their ectopic pregnancy as measured by the disappearance of hCG from plasma and the radiologic appearance of the fallopian tube 3 months after methotrexate therapy.

These investigators are not the first to report the successful use of methotrexate for the treatment of ectopic pregnancy. Tanaka et al.[1] described the successful treatment of an interstitial ectopic pregnancy with subsequent demonstration of a patent fallopian tube in 1982; Farabow et al.[2] reported the successful treatment of a woman with a cervical pregnancy using methotrexate in 1983. In Farabow's case, surgical treatment would have mandated a hysterectomy and consequent loss of reproductive function. We reported the successful treatment of a woman with a tubal ectopic pregnancy 3 months after a tubal anastomosis.[3] In our case, hCG disappeared from serum 15 days after the initiation of methotrexate.

Ory and associates are the first investigators to develop a protocol for selecting and managing women with early ectopic tubal pregnancies, and they are the first to report a series of women treated with methotrexate. Five of the six women in their series (83%) had complete resolution of their ectopic pregnancy.

Methotrexate has been used for the treatment of gestational trophoblastic disease for nearly 30 years. Li et al.[4] first reported the use of methotrexate for the treatment of choriocarcinoma, choriadenoma, and hydatidiform mole in 1956. Since that report, methotrexate has been the standard treatment for gestational trophoblastic disease. Why has it taken so long to apply this successful medical therapy to the problem of ectopic pregnancy? Ory and associates answer this question in their paper. Advances in the technology of sensitive and specific radioimmunoassay for hCG and improved resolution of ultrasonography have recently enabled the obstetrician to suspect an ectopic pregnancy before the pregnancy ruptures from its implantation site. The diagnosis of suspected unruptured ectopic pregnancy can be confirmed by diagnostic laparoscopy. Bryson[5] made a prospective study of 81 women by means of hCG assay and ultrasonography; he reported an accuracy of 100% in selecting women with an early, unruptured ectopic pregnancy.

Before the application of these diagnostic tools, ectopic pregnancy was only suspected when a woman presented with signs of hemoperitoneum from a ruptured fallopian tube. In these women, surgical resection of the ruptured fallopian tube was the only available treatment.

With the improvement in the clinician's ability to make the diagnosis of an early unruptured ectopic pregnancy, salpingectomy has given way to linear salpingotomy or "milking" the pregnancy from the tube.[6] The long-term success rate of this treatment, that is, repeated ectopic pregnancy or improvement in fertility is still uncertain. However, Rivlin et al.[7] and Richards[8] reported persistent trophoblastic tissue following conservative surgical management, which subsequently necessitated salpingectomy for their patients. Perhaps methotrexate treatment would have spared the fallopian tubes of these women.

It is important to point out the rising incidence of ectopic pregnancy in the United States. Rubin et al.[9] reported that the incidence of ectopic pregnancy rose from 4.5 per 1000 reported pregnancies in 1970 to 9.4 per 1000 reported pregnancies in 1978. The risk of an ectopic pregnancy is highest in nonwhite women and women aged 35 to 44 years. The rising incidence of ectopic pregnancy has been attributed largely to the rising incidence of gonococcal and chlamydial salpingitis.

I would like to ask the authors two questions. First, in Table I of the article, all subjects were listed as having had an ectopic pregnancy. Was this the ectopic pregnancy managed with methotrexate by the authors, or had these subjects had a prior ectopic pregnancy? If the ectopic pregnancy treated with methotrexate was the second ectopic pregnancy for each subject, did this fact influence the patients and the authors to select medical rather than surgical theapy? Would the authors select methotrexate therapy for a first ectopic pregnancy?

Second, the authors obtained a hysterosalpingogram on each subject 3 months after the completion of medical therapy. What was the result of the posttreatment hysterosalpingogram?

In my opinion this study is an important contribution to our methods for management of ectopic pregnancy. With improved diagnostic tools to select women with ectopic pregnancies before rupture, it is reasonable to think that methotrexate therapy could become the primary method of treatment for this pregnancy complication. Moreover, this study should encourage obste-

tricians to consider more carefully the risk factors for ectopic pregnancy and to perform early ultrasonography in women at risk for ectopic pregnancy. Finally, with the case reports of persistent trophoblastic tissue in women undergoing conservative surgery for ectopic pregnancy, we should obtain serum hCG titers following conservative surgery to select women with persistent trophoblastic disease and treat them with methotrexate. Holtz[10] has constructed disappearance curves of hCG in women following linear salpingotomy.

The authors should continue these studies to enlarge their series and evaluate the long-term consequences of methotrexate therapy. Other investigators should make independent evaluations of methotrexate therapy for unruptured ectopic pregnancy.

DR. LOUIS WEINSTEIN, Tucson, Arizona. Since many obstetric and gynecologic therapies are controversial, it is a pleasure to be able to discuss a manuscript in which there is no controversy regarding the proposed therapy. Simply stated, the use of a potent antineoplastic, antimetabolite drug, methotrexate, for treatment of an ectopic pregnancy is inappropriate and potentially dangerous.

The authors have presented a report of six patients with the laparoscopic diagnosis of an ectopic pregnancy who received a four-dose course of intravenous methotrexate for therapy. The facts of the six cases are as follows. One patient developed an acute abdomen requiring operation and hemoperitoneum on day 12 of therapy, requiring an exploratory laparotomy. Two patients had abdominal pain and a significant hemoglobin drop after their course of methotrexate therapy and required blood transfusions. One of these episodes occurred 4 weeks after the start of therapy. All of the remaining patients experienced stomatitis and/or elevated liver enzyme levels. Of the three patients stated to have a successful course of therapy, one appeared to be experiencing a tubal abortion at the time the treatment was started. These data therefore reveal a success rate of 33% and a morbidity rate of 100%.

It is difficult to determine from the report the average length of hospital stay, but it was at least 8 days or longer, since the four-dose course of methotrexate was given every other day. Are the authors advocating an 8- to 10-day hospital course for an ectopic pregnancy or do they want the clinician to treat the patient with an ectopic pregnancy as an outpatient, returning to the office every other day for intravenous methotrexate therapy?

Equal to my concern for the inappropriateness of the methotrexate therapy is the ethics of performing this study. Before the start of the methotrexate therapy each patient underwent a laparoscopy to confirm the diagnosis of the ectopic pregnancy. I am baffled in my attempt to visualize how an institutional review board could approve such a project, and how adequate informed consent could be given to these patients. I do not understand what would motivate a patient to agree to a hospital stay of more than 8 to 10 days, a general surgical procedure, daily blood drawing, and the administration of a potent antineoplastic agent when a simple surgical procedure could cure her problem.

The last paragraph of the article states that although "it is unlikely that methotrexate therapy will become the most common treatment for ectopic pregnancy . . . our preliminary experience suggests that the agent can provide a safe and relatively effective alternative to surgery. . . ." I wish to remind the authors of a statement from the nineteenth century scientist, Jules Henri Poincaré, who said, "Science is built up with facts, as a house is with stones. But a collection of facts is no more a science than a heap of stones is a house."

I should appreciate it if the authors would address the following points: (1) What was the length of hospital stay for the five patients? (2) What was the cost of total therapy for each patient and who was responsible for the bill? (3) Was this study reviewed by their institutional review board and was any difficulty encountered in getting approval? (4) How and by whom was the study presented to the patient? (5) How long was the consent form and was any financial renumeration offered to the patient for her participation?

DR. HARRY K. WADDINGTON, Olympia Fields, Illinois. In addition to the suggestion of taking salpingograms, in spite of the penetrative process of laparoscopy, I think we should have been shown photographs of the interior of these abdomens taken by laparoscopy of the four patients who did not have laparotomy. Otherwise, this is an excellent presentation.

DR. ROBERT A. MUNSICK, Indianapolis, Indiana. I think Dr. Weinstein is right, that it is unusual and

strange that this was apparently approved by an institutional review board; but the fact is, it was. Therefore I wonder why there was no control group to determine whether they also had an approximately 50% success rate, which I believe they probably would have had with diagnoses made this early.

I also would like to remind the authors that about one in 300 ectopic pregnancies will have a concomitant combined intrauterine pregnancy, and I would hate to give methotrexate to that patient.

Dr. Eduard Eichner, Cleveland, Ohio. First of all, I disagree with Dr. Weinstein in this regard. It was a tough situation, but if you use private patients, I have found in my research over many years that a private patient will do almost anything the physician wants her to do and will sign all the papers necessary; if you can explain to the pateint that this is a method that might save other patients' lives and major operations, they will go along with it willingly.

I am interested in two other things: I took my early training at a time when we were not permitted to operate on an unruptured ectopic pregnancy because that was considered to be an abortion. Now, with the right-to-life movement getting very strong, the destruction of a fetus in the abdomen by destruction of the chorionic tissue and so on, will bring them to the fore. Will the hospital be able to handle it?

The final question I want to ask concerns reconstruction of the tube or the viability of the tube. Did any of these patients have a successful intrauterine pregnancy after the procedure?

Dr. Madhwa Raj, New Orleans, Louisiana. This is a very interesting presentation. It occurred to me that perhaps the best course would be to look for suitable animal models that we could use experimentally without all these problems. As you know, there have been several models in the works for ectopic production, including one in the primate, so I would put before this audience the suggestion that we seriously consider doing some more basic work on primates and making sure that these hurdles can be safely crossed.

Dr. Ory (Closing). I appreciate the spirited comments.

Regarding Dr. Bates' initial questions regarding whether or not a previous ectopic pregnancy changed our management, as I pointed out, five of the six did have previous ectopic pregnancies; two of them were managed conservatively and three with salpingectomies. Patients who had had conservative procedures and had recurrent ectopic pregnancies were certainly more amenable to trying a different approach. We presented the option that if the patient had a recurrence in an affected oviduct, it might be more desirable for them to have the tube removed, and some of the 52 excluded patients were omitted on that basis.

Regarding the hysterosalpingograms, I had hoped to have six of them completed and available to show you. Many of these subjects came into the study rather late and are just reaching their 3-month point now. In the two that we have performed, one in the first group had preservation of tubal patency. The second one, who was subject 5, did have distal tube occlusion. There was quite a bit of adhesive disease noted at the time of initial laparoscopy, however.

Regarding Dr. Weinstein's comments, the length of hospitalization ranged from 8 to 25 days. One subject, No. 5, was readmitted after discharge when additional concerns regarding a gradually falling hemoglobin level developed.

This was a pilot study. It was funded by a National Institutes of Health Clinical Research Center grant, in part. In order to undertake this, we felt it was critical to monitor these patients as intensively as possible, which we did. We are not proposing that this be done on an outpatient basis. As I mentioned, I think it will be best suited for patients with very early ectopic pregnancies. I do not think we have enough experience, as yet, to say whether an outpatient modality will be viable, but it may well be an option.

As I mentioned, the cost was borne in part by the Clinical Research Center and in part by the patients themselves. The total cost including laparoscopy, hospitalization, testing, and so on, ranged from about $6,200 to $8,500, which is consistent with the comprehensive cost of salpingectomy or linear salpingotomy in our institution.

The protocol was formulated after 18 months of work. The FDA was involved in developing the protocol, and we were granted the first investigational new drug license in the United States to test the use of methotrexate for this purpose. They had several suggestions regarding monitoring toxicity, but they were enthusiastic about this application. Lederle, the manufacturer of methotrexate, was also involved in obtaining the license and was quite helpful as well.

Locally, the protocol was approved by separate hospital and university institutional review board committees, and there was extensive modification over a 6-month period of time. There was no outright objection to implementing the protocol, only suggestions for additional refinement.

I personally presented the protocol and consent form to each patient. There was no remuneration offered whatsoever. Photographs were taken of all patients at the time of laparoscopy.

The issue of the control group is an interestng one, and one that we discussed at length. There is a strong clinical impression that the incidence of spontaneous tubal abortion is more frequent than we suspect. No one, at least when we initiated this study 18 months ago, was prepared to simply observe patients with ectopic pregnancies without treatment. Our institutional review board did object and were also unwilling to subject patients to that. Consideration is being given to observant management, and if patients with suspected ectopic pregnancies are followed for a few days with decreasing quantitative hCG levels, it may be reasonable to delay surgery and see whether these patients will not undergo spontaneous resolution. In fact, we have had the opportunity to observe this phenomenon

in four or five patients at Northwestern, and there are clinical protocols in progress to test this on a broader scale.

With regard to the risk of inadvertently administering methotrexate to a woman with concomitant intrauterine pregnancy, that possibility was excluded by ultrasound studies. We did not routinely submit these patients to curettage because we were interested in seeing whether they did pass decidual casts and whether that might be clinically useful in monitoring their response.

We have not had any subsequent term pregnancies in this group; none of these women subsequently conceived. Each was instructed to use contraception for 3 months after the study. This was to enable the methotrexate to be cleared and to allow the oviduct to completely heal.

Finally, regarding Dr. Raj's comment about the animal model, I understand the rabbit is a reasonable model to work with in ectopic pregnancies. However, I think the clinical parameters we were evaluating here could not have been satisfactorily tested.

Correlation of neonatal acid-base status with Apgar scores and fetal heart rate tracings

Frank O. Page, M.D., James N. Martin, M.D., Sue M. Palmer, M.D., Rick W. Martin, M.D., John A. Lucas, M.D., G. Rodney Meeks, M.D., Edsel T. Bucovaz, Ph.D., and John C. Morrison, M.D.

Jackson, Mississippi

In this study the immediate neonatal acid-base status, obtained via a double-clamped segment of umbilical cord, in 75 term, singleton vaginal deliveries was compared to electronic fetal heart rate recordings and Apgar scores. Of 75 neonates, 59 had 1-minute Apgar scores ≥7 and 52 had an initial pH >7.20. Six of the 16 neonates with a 1-minute Apgar score <7 demonstrated a low pH (<7.20). At 5 minutes only eight of 75 neonates had Apgar scores <7 with six of the eight having pH values <7.20. Of those neonates with Apgar scores ≥7 and pH <7.20 (seven neonates at 1 minute, two at 5 minutes), none had metabolic acidosis. Eighteen fetal heart rate tracings were considered abnormal; acidosis was confirmed in eight (44%) by pH criteria, yet only three of the eight neonates had low Apgar scores. Our investigations suggest that the combination of fetal heart rate monitoring, cord blood pH, and Apgar assessment is better than any one parameter alone as an evaluation of fetal status just after delivery. (Am J Obstet Gynecol 1986;154:1306-11.)

Key words: Neonate, acid-base status, Apgar scores, fetal heart rate, correlation

Before the development of Apgar scoring, there was no systematic method for neonatal assessment immediately after birth. The original intentions of this scoring system were to predict immediate neonatal survival, to evaluate various methods of resuscitation, to compare the early perinatal experience in different hospitals, and to ensure closer observation of the infant during the first few minutes of life.[1] In the 30 years since its introduction, the Apgar score has become one of the most important evaluation systems in medicine for the early identification of neonatal complications.[2]

Unfortunately during the past two decades neonatal Apgar scores at 1 and 5 minutes have been considered by some to reflect intrauterine asphyxia and to predict long-term neurological outcome. The Apgar score, however, is often poorly correlated with other indicators of intrauterine well-being.[3] To better and more accurately reflect intrauterine fetal status and distress, many other evaluation methods have been studied, including cord blood pH, lactate, arginine vasopressin, isoenzymes, and catecholamines as well as fetal scalp blood sampling, fetal scalp stimulation, passage of meconium, and electronic fetal heart rate assessment. Of these methods, electronic fetal heart rate assessment is a good predictor of fetal health but is associated with a high false positive rate when forecasting asphyxia and

Table I. Apgar scores versus pH values

Apgar score	*pH*	*1 min*	*5 min*
≥7	≥7.20	52*	65
	<7.20	7	2
<7	≥7.20	10	2
	<7.20	6	6

*p < 0.02 at 1 minute.

Table II. Abnormal fetal heart rate tracings (n = 18)

		Apgar score ≤7	
pH	*n*	*1 min*	*5 min*
≥7.20	10	1	0
<7.20	8	3	1
>7.20, <7.30	15	1	0

is even more deficient in predicting long-term outcome.[4,5] Neonatal arterial blood gas and pH assessment in the nursery correctly reflect acidosis but usually do not correlate well with Apgar scores or electronic fetal heart rate findings, perhaps in part because they are usually obtained remote in time from the delivery process.[6] Umbilical cord blood gas values at delivery have been correlated with Apgar scores, are easier to obtain than fetal scalp samples, and are more timely than later neonatal studies.[7] The purpose of this study was to investigate the correlation of 1- and 5-minute Apgar scores with umbilical arterial blood gas values and electronic fetal heart rate recordings.

Material and methods

This prospective study was performed during a 3-month period from July 1, 1984, to September 30, 1984, in the perinatal unit of the University of Mississippi Medical Center. The umbilical arterial acid-base status, Apgar scores, and intrapartum electronic fetal heart rate tracings were obtained from 75 randomly selected, singleton, term, vaginal deliveries.

An 8-inch segment of umbilical cord was doubly clamped immediately after delivery of the infant. Blood from the umbilical artery was withdrawn into a 1 ml plastic syringe that had been preflushed with a heparin solution (1000 units/ml). Each blood-filled syringe was placed in ice for transport to the laboratory. Arterial blood gases and pH determinations were performed within 20 minutes of delivery with an IL-813 blood gas analyzer. The standard definition of neonatal acidosis with a pH value of <7.20 was used.[8] Apgar scores were determined 1 and 5 minutes after birth by trained delivery room nurses (who assign scores to all infants). An Apgar score ≥7 was considered normal.

All patients were monitored electronically by means of a fetal scalp electrode during the intrapartum period. The electronic fetal heart rate tracings were interpreted in a blinded fashion by an observer without knowledge of the intrapartum course, blood gas data, neonatal outcome, or Apgar scores. Any of the following alterations in the fetal heart rate tracing were considered abnormal: late decelerations after 50% of contractions during 30 minutes, significant variable decelerations (<60 bpm for 60 seconds), minimal beat-to-beat variability for 30 minutes (<3 bpm), and/or prolonged bradycardia (<100 bpm for >2 minutes).

The electronic fetal heart rate recordings and newborn hospital records were examined in order to determine any correlation with Apgar scores and neonatal acid-base values.

The χ^2 analysis was used to determine statistical significance at a level of <0.05.

Results

Study subjects ranged in age from 14 to 39 years with a mean of 23 years. The average gestational age was 39 weeks with a range of 37 to 42 weeks. Forty-eight of the infants were delivered spontaneously while 27 were delivered with elective outlet forceps. There were 39 male infants included in the study and 36 female infants. One third of the patients were delivered while under regional anesthesia while others received pudendal, local, or no anesthetics. None of these factors were significantly different when normal versus abnormal Apgar scores, cord pH values, or electronic fetal heart rate tracings were compared. Review of the neonatal hospital course infant charts revealed no significant morbidity, except for one infant with a major congenital anomaly that required a corrective surgical procedure. Four infants had transient hyperbilirubinemia that required phototherapy.

Fifty-nine of the 75 neonates (79%) had 1-minute Apgar scores of ≥7 (Table I). Of the 59 neonates, seven (12%) had an umbilical arterial pH of <7.20, while 52 (88%) had an initial pH of ≥7.20. When the Apgar score was ≥7 there was a significantly greater frequency of pH values >7.20 than expected by chance alone (p = 0.02). Sixteen of the 75 neonates (21%) had a 1-minute Apgar score of <7. Ten of the 16 (62%) with low Apgar scores had an initial pH of ≥7.20 and six (38%) had an initial pH of <7.20. When the 5-minute Apgar scores were studied, only eight of 75 infants had scores ≤7. Of these eight infants, six had pH values <7.20, while only two of 67 infants (2.9%) had 5-minute Apgar scores ≥7 and were acidotic by pH criteria. Review of the acid-base status in both of these neonates revealed an acute respiratory acidosis (a low pH with a high P_{CO_2} and a normal base deficit).

There were 18 electronic fetal heart rate recordings

that were considered abnormal by the previously stated criteria. Acidosis was confirmed by pH criteria in eight of these 18 infants (44%) (Table II). If the 1-minute Apgar score was considered, only three of the eight acidotic infants would have been identified if one assumes Apgar scoring to reflect acidosis. Of 18 abnormal tracings, 15 (83%) were associated with pH values >7.20 but <7.30.

Comment

The value of the Apgar score as a systematic method to generally assess newborn well-being is accepted as an extremely important tool.[9] Because the Apgar scoring system does not often reflect the degree of acidosis at delivery, its value as an indicator of perinatal asphyxia has been questioned.[3, 5, 10] Sykes et al.[3] summarized the findings of these relationships in more than 200 consecutive deliveries. In that study, 21% of the neonates with a 1-minute Apgar score of <7 had severe acidosis at delivery as evidenced by an umbilical arterial pH of <7.10 and a severe base deficit. On the other hand, 75% of the infants with a significant acidosis had an Apgar score ≥7 at 1 minute. In our study 38% had acidosis if the Apgar score was <7 at 1 minute.

Hon and Khazin[11] have shown that fetal scalp pH correlates with Apgar scores but that there is considerable overlap between pH values for infants with high and low Apgar scores. Their work suggests that if pH <7.20 is used to delineate acidosis, 15% to 20% of neonates have a pH >7.20 yet have Apgar scores of 1 to 6 at 1 minute. Fields et al.[12] reported a comparative study of umbilical cord pH values and Apgar scores in 172 singleton neonates. When the Apgar score was <7, 56% of the neonates had a normal pH value, which is very close to the 62% in our own study.

Similarly, umbilical cord pH has been correlated with electronic fetal heart rate and outcome at delivery.[4] Unfortunately, even in the face of high risk pregnancies, Low et al. found that fetal metabolic acidosis was present in only 48% of those with abnormal fetal tracings, similar to the 44% in the current study. The severity of fetal hypoxia as manifested by a significant metabolic acidosis is also a poor predictor of neurological outcome. Low et al.[13] found that only 56% of fetuses with severe fetal hypoxia had newborn encephalopathy. Therefore, acid-base studies alone do not appear to be excellent predictors of long-term outcome nor are they well correlated with newborn condition at birth or with electronic fetal heart rate tracings.

Neurological follow-up of infants with low Apgar scores has likewise been unrewarding. Nelson and Ellenberg[14] studied the correlation of Apgar scores and cerebral palsy in approximately 40,000 infants who were followed up for 7 years. Low Apgar scores were risk factors for cerebral palsy, but 55% of children with later cerebral palsy had Apgar scores of 7 to 10 at 1 minute and 73% had scores of 7 to 10 at 5 minutes. Of the children who had Apgar scores of 0 to 3 at 10 minutes or later and survived, 80% were free of major handicap at early school age.

Our study indicates that intrapartum fetal monitoring patterns and Apgar scores, which are used retrospectively by some to predict biochemical asphyxia in the neonate, have a high incidence of false positive results. Neonates with Apgar scores <7 or abnormal electronic fetal heart rate can be assessed by use of an umbilical arterial analysis to ascertain the presence of acidosis and to differentiate between metabolic and respiratory acidosis. This adjunctive information, while not specific in and of itself for fetal distress, can be used in conjunction with the Apgar score and electronic fetal heart rate to give a better assessment of neonatal condition than that with any one modality alone. We recommend the use of umbilical cord acid-base assessment when ominous electronic fetal heart rate tracings are present, unsuspected neonatal distress is noted at delivery (Apgar score < 7), a birth weight <1500 gm is suspected, or other signs of intrapartum distress have been noted (meconium). Although most of the infants in these categories develop normally after birth, these are the conditions that relate to abnormal neurological outcome and litigious action.

Discussion

Dr. Marvin L. Hage, Durham, North Carolina. Assessment of the health of the newborn infant and prediction of future morbidity and mortality is a critical function of perinatal research and practice. The combined use of electronic fetal monitoring, Apgar scores, and umbilical arterial pH has been described in this paper as well as by others.[1-6] Findings of these studies have shown overall agreement among the three tests; however, the specificity of the tests as to long-term outcome (mortality or morbidity) has been low.[7-9] The controversial question remains as to the addition of umbilical arterial blood gas biochemical testing. Specifically, I would like to ask the authors to comment on the following:

1. Would it be better to measure base excess since that has been correlated with neonatal encephalopathy?[10]
2. Would they recommend simultaneous measurements of maternal pH?[11]
3. Were there any technical problems in performing the test, particularly in obtaining the sample, clotting, or costs of the tests?
4. For institutions that do not have easy accessibility to 24-hour blood gas evaluation, would they recommend any other techniques?
5. What would the authors recommend for premature births, a high-risk area for both neonatal death and morbidity?[12]
6. Do the authors feel that part of the lack of agreement between the different methods could be explained by lack of precision of interpretation of the fetal monitor strip or assignment of the Apgar score?

Dr. Divina J. Santos, Cincinnati, Ohio. Since 1953, when Virginia Apgar proposed the use of the now famous Apgar score, several advances have occurred in the practice of obstetrics; among them are electronic fetal and uterine monitoring and scalp and umbilical vessel sampling for pH and blood gas analysis. As a result of pregnancies being increasingly planned, wanted, and fewer in number, each pregnancy is more precious and there is greater expectation of a perfect outcome. Any deviation from the expected perfect result can lead to a medicolegal litigation. There is a long statute of limitation. A child up to the age of 21 can now sue the obstetrician for wrongful birth.

Through the years, the interpretation of the Apgar score has been expanded to include using it to predict occurrence of intrapartum birth asphyxia and subsequent long-term neurological outcome. Recently, however, many investigators have questioned the ability of the Apgar score to make these predictions. As a result, there is increasing use of intrapartum scalp sampling and umbilical blood analysis for pH and blood gas values. The estimation of base deficit allows differentiation between respiratory (acute asphyxia) and metabolic (chronic or long-standing asphyxia). The authors of this article attempted to find a correlation between the neonatal acid-base status, Apgar scores, and fetal heart rate tracing.

This article raises several questions:

1. Who attended the deliveries? Who performed the resuscitation? How many babies had meconium-stained amniotic fluid, and how many had a nuchal cord? Was there a relationship between the low Apgar scores, acidotic pH, and any of these variables?
2. Was there a higher incidence of elective outlet forceps in those that had an abnormal fetal tracing?
3. Was there a greater number of abnormal tracings in those that had hypotension during regional anesthesia?
4. What were the range and average length of fetal monitoring? Was the entire record examined? Of those 18 abnormal tracings, did the babies that also had low Apgar scores have a worse tracing than those that did not? Were the abnormalities in the tracing more pronounced in the last 30 to 60 minutes before delivery in those babies with low Apgar scores and pH <7.20?
5. Were there any medications given during labor that could affect the Apgar score, such as narcotics, tranquilizers, or magnesium sulfate?
6. Was the base deficit estimated in all cases? Did the babies with a pH <7.20 have metabolic or respiratory acidosis?

Table I. Mean differences from control (time 0) at 15 minutes (n = 14)

	Venous	*Arterial*
pH	−0.006	−0.022
P_{CO_2} (mm Hg)	0.143	0.628
P_{O_2} (mm Hg)	0.414	0.964

7. Of those infants that had a pH <7.20, how low were the Apgar scores?

8. What was the base deficit in those babies that had abnormal fetal heart rate tracings and those with low Apgar scores? Were those babies with large base deficits the same ones that had persistently low 5-minute Apgar scores?

Because the Apgar score does not always indicate presence or absence of intrapartum asphyxia, some institutions have adopted a policy of obtaining umbilical cord pH and blood gas values in selected cases or routinely in all deliveries. Since each determination costs approximately $25.00, it may not be cost effective to do this laboratory test for all deliveries.

We recently studied the stability of pH and blood gas values in a doubly clamped umbilical cord left at room temperature. We found that sampling of the umbilical artery and vein can be delayed up to 15 minutes without invalidating the values of the pH, P_{CO_2}, and P_{O_2} when compared with the values obtained from umbilical blood samples at birth. Table I shows the mean differences in pH, P_{CO_2}, and P_{O_2} of umbilical venous and arterial samples collected at 15 minutes when compared with pH and blood gas values obtained immediately at birth. There was no statistically significant difference noted when the results of samples collected at 15 minutes were compared with those of samples collected immediately after delivery.

In most instances, 15 minutes should be ample time to assess the newborn infant, assign the Apgar score, and decide if umbilical arterial pH and blood gas values will be necessary to elucidate some confusing clinical picture and establish the acid-base status at the time of delivery.

I agree with the authors' conclusion that we should utilize all three methods available in our armamentarium to assess the neonate, not only immediately at delivery but also prospectively and retrospectively, if we are to continue to improve the quality of care we render our patients and their babies.

Dr. Chang Y. Lee, Detroit, Michigan. We are faced with the necessity of reappraising the tools used for the diagnosis of fetal asphyxia. The important question asked by many investigators is does fetal asphyxia diagnosed by these tools indeed predict the development of neurological abnormalities? Since I am the third discussant assigned to this preliminary report, instead of dissecting the paper, I would like to extend my discussion to questions regarding fetal asphyxia and the development of neurological deficit.

In a prospective study of 1210 consecutive deliveries, Sykes et al.[1] found that only 21% of the neonates with a 1-minute Apgar score <7 and 19% of the neonates with a 5-minute Apgar score <7 had a severe acidosis (umbilical cord blood pH ≤7.10 and base deficit ≥13 mmol/L). The majority of neonates (86%) with severe acidosis had an Apgar score of 7 at 5 minutes. Silverman et al.[2] also found similar results with more than 1000 neonates. It is apparent in these studies that physical fetal depression (low Apgar scores) occurs with severe and prolonged asphyxia in the healthy fetus.

In a collaborative perinatal project, Nelson and Ellenberg[3] evaluated Apgar scores as predictors of chronic neurological disability. Among 390 infants with Apgar scores of 0 to 3 at 10 minutes or later, 270 infants died before their first birthday. Of the remaining 120 infants, 99 were followed up to 7 years of age; 87 were free of disabling cerebral palsy and only 12 (12%) children developed cerebral palsy. This study demonstrated that the outcome of this extreme asphyxia was either death or apparent intact survival.

After this study of 760 asphyxiated neonates as judged by Apgar scores and abnormal acid-base and blood gas status, Brown et al.[4] noted: "Asphyxia occurs in 54 per 1,000 live-born infants of whom only 7 are likely to be at risk of permanent brain damage. The dilemma of the obstetrician is that he has no way of knowing antenatally which are the 7."[5] We are, however, making every effort prenatally to identify these seven. In the study by Haesslein and Niswander,[6] among 80 term infants born after intrapartum asphyxia, neurological damage occurred in only 5 with risk factors of chronic intrauterine asphyxia including postdates (three) and intrauterine growth failure (two). There is mounting evidence that chronic asphyxia or repeated acute episodes of asphyxia superimposed on chronic asphyxia lead to permanent brain injury.

Low et al.[7] assessed causes of newborn encephalopathy. Neonatal respiratory complications and infections were found to be the causes of severe encephalopathy in 66% of newborn infants compared with 22% caused by fetal asphyxia. A normal range of acid-base status at umbilical cord blood sampling may protect us from litigious action in some cases. I strongly support the recommendation of obtaining cord blood for protection in the current medicolegal environment. I encourage the authors to continue their study with long-term follow-up.

DR. JOHN L. DUHRING, Toledo, Ohio. I would like to ask the authors if any type of emergency, perhaps a profoundly defective baby or a depressed neonate or anything that would interfere with the collection of the cord blood specimen, affected their studies? I think Dr. Santos touched on this. I would like to hear their experience.

DR. JOHN GARBACIAK, Cleveland, Ohio. Will the authors state specifically what method they used for the pH determination and, if they can give reasons, why they chose the umbilical arterial blood as opposed to the umbilical vein?

DR. CHARLES A. WHITE, New Orleans, Louisiana. There was a multiplicity of questions raised by the formal discussants. My question is of relatively minor importance, but the authors mentioned scalp stimulation under fetal assessment. I wonder if the authors would amplify on that.

DR. JAMES MAURER, Phoenix, Arizona. While the presence of meconium may be somewhat nonspecific, I wonder if any of the acidotic babies were born without the presence of meconium.

DR. MARTIN (Closing). All of our deliveries at the University Medical Center at Mississippi were attended by the house staff. There were two private patients attended by faculty. In general these were normal deliveries and the infants were attended by obstetrics personnel for resuscitation. Pediatrics personnel were consulted if there was a problem.

Dr. Hage had questions about technical problems. We had no clotting or other methodologic problems. Our average charge to the patient is $37. I think that is reasonable. One could just obtain the arterial pH, but we believe the base excess, Po_2, and Pco_2 are important tools in the evaluation.

There was a concern about the private practitioner in a smaller hospital. If the infant is compromised, the odds are good that the pediatrician will be evaluating blood gases anyway, so we do not feel this would be any extra inconvenience for the laboratory personnel to analyze the cord blood sample.

Also, as far as maternal blood gases are concerned, we did not routinely determine those because we had normal mothers without asthma or any pulmonary disease or ketoacidosis. It would be advisable to obtain a maternal acid-base study if you suspect an abnormality.

In cases of fetal compromise, since most of the authors whose articles I have read have recommended immediate clamping of the umbilical cord for acid-base studies, I do not think that this would interfere with obtaining umbilical cord samples. We would obtain an umbilical arterial specimen, since it has been shown to correlate better with scalp pH. Also it makes more sense to sample blood coming from the fetus to the placenta as it will more adequately reflect fetal status than blood from the placenta returning to the fetus. Actually, I think there is a 0.1 higher difference in the pH.

The scalp stimulation test as described by Dr. Miller involves manipulating the fetal scalp and looking for a rise in fetal heart rate similar to that with the nonstress test. The specific method used was to put an Allis clamp on the scalp to see if the fetal heart rate acceleration occurred after that.

We had four infants with meconium. Three were normal; one had an abnormal fetal heart rate tracing. All had normal pH values. There were two infants with nuchal cords and both had normal fetal heart rates and Apgar scores. There were certain drugs administered that could affect the variability and the heart rate tracing. Demerol was given in small amounts, the maximum being three 25 mg doses in one patient. We did have three patients with pregnancy-induced hypertension. They received magnesium sulfate but also had normal acid-base studies in the fetus.

Dr. Hage pointed out that there is disagreement about the interpretation of the fetal heart rate tracings and Apgar scores. These are generally methods that most of us are using to evaluate the fetus. We are looking for more objective and less subjective means of evaluating the fetal status, and that supports our claim that umbilical cord studies should be done.

Dr. Santos made a good point, that we could delay obtaining the blood sample for up to 15 minutes after delivery. Thus we could go back and look at the cord blood gas values and assess our care, should a problem be detected in a baby after delivery.

Upper genital tract changes and infertility in diethylstilbestrol-exposed women

Raymond H. Kaufman, M.D., Ervin Adam, M.D., Kenneth Noller, M.D., John F. Irwin, M.D., and Milton Gray, M.D.

Houston, Texas, and Rochester, Minnesota

A possible relationship of upper genital tract abnormalities in the diethylstilbestrol-exposed woman and infertility was studied. Six hundred thirty-two women had roentgenography performed. Three hundred sixty-seven of these women were not using contraception and were actively trying to become pregnant. One hundred thirty-four (36%) of these women reported difficulties conceiving for a period of 1 or more years. Seventy-three percent of these women had abnormal hysterosalpingograms. The frequency of abnormal x-ray films in the women who did conceive within 1 year was essentially the same (74%). Furthermore, a similar number of women with normal x-ray films (37%) had difficulty conceiving as did women with abnormal x-ray films (36%). When specific hysterosalpingographic abnormalities were related to the presence or absence of infertility, it was observed that the presence of a constriction of the upper uterine cavity resulted in a 2.26-times greater likelihood that a woman would not be able to conceive. If a T-shaped uterus was found in association with constriction of the upper uterine cavity, the odds ratio for inability to conceive was found to be 2.63. (Am J Obstet Gynecol 1986;154:1312-8.)

Key words: Diethylstilbestrol exposure, hysterosalpingogram, uterine abnormality, infertility

Pregnancy outcome in women exposed to diethylstilbestrol before birth is significantly worse than in the nonexposed patient. An association between upper genital tract abnormalities and this poor pregnancy outcome has been found.[1] There is disagreement, however, regarding the frequency of infertility in the diethylstilbestrol-exposed woman compared with the unexposed individual. Barnes et al.[2] have reported that infertility, which was measured in pregnancies achieved, did not differ between women exposed to diethylstilbestrol and a control population. Bibbo et al.[3] and Herbst et al.,[4] however, have noted an increased occurrence of infertility in the diethylstilbestrol-exposed woman. The present study was undertaken to investigate whether there is an association between structural changes of the upper genital tract and infertility. The answer to two questions was sought. First, is there an association between any upper genital tract abnormalities and the ability to conceive? Second, are specific structural changes of the upper genital tract related to infertility?

Material and methods

The patients studied were selected from women who had been enrolled in a national study funded by the National Cancer Institute to identify and follow up women exposed in utero to diethylstilbestrol (Diethylstilbestrol Adenosis or DESAD Project). Patients were recruited from two of the centers participating in this program—Baylor College of Medicine, Houston, Texas, and the Mayo Clinic, Rochester, Minnesota. The details of patient recruitment and selection for the DESAD Project were presented earlier.[5] The details of patient recruitment for hysterosalpingography have also been published.[1]

The methods of obtaining maternal and patient history, as well as findings of the first examination,[6,7] have been reported in previous DESAD communications as has the technique of hysterosalpingography and uterine evaluation.[8] Before initiation of the study, the investigators from Baylor College of Medicine and the Mayo Clinic standardized the x-ray review in order to ensure that the evaluations were consistent. The majority of the x-ray films were reviewed only at the center where they were performed. The shape, size, and contour of the uterine cavity were evaluated. Uterine defects, contour and appearance of the cervix, and changes in the oviducts were also recorded. In particular, the following abnormal conditions were documented during review of the films: cavity shape as T-shape, arcuate, hypoplastic, wide lower segment, bicornuate, unicornuate, constriction of upper-middle-lower segment, cornual constriction; intrauterine de-

fects as synechiae, diverticula, filling defect, irregular margins, ridges; oviducts—constriction, irregular borders, loculation, shape, patent or nonpatent.

At the time of each annual follow-up visit, the patients completed a health-history questionnaire. This questionnaire included information relative to sexual activity, contraception, desire to become pregnant, difficulty in conceiving, and pregnancies achieved. The information regarding difficulty in conceiving, infertility, and workup for infertility was given by the patients and was not verified by physician's records.

The manner of selection of patients for enrollment in a study such as this can influence to a significant degree the findings noted, as has been clearly demonstrated in prior DESAD reports.[1, 5, 6] The patients entered into the hysterosalpingogram study were selected from each of the four participant sources, the most reliable and unbiased of which was from the record review category. At Baylor, 41% of the walk-in and referral and 28% of the record review participants volunteered for the hysterosalpingogram study. At Mayo, only record review participants were asked to volunteer, and 36% of these women agreed. However, in the attempt to evaluate the relationship of possible infertility to structural changes of the upper genital tract, it was felt that combining all of the groups (record review, walk-ins, and referrals) for this study would not introduce a significant selection bias. Furthermore, since the data for both Baylor and the Mayo Clinic were similar, the data from both of these institutions were also grouped together. There was some degree of self-selection bias since a higher percentage of women who volunteered for the hysterosalpingogram study had difficulties conceiving compared with those women who did not participate in this study.

Information regarding attempted and successful pregnancies was available for 632 of the women in whom hysterosalpingography was performed. Three hundred sixty-seven of these women were not using contraception and were actively trying to achieve pregnancy. Information relative to success in achieving pregnancy, difficulty achieving pregnancy, and inability to become pregnant was related to the hysterosalpingographic findings.

Statistical analyses were done by means of the χ^2 test and Haldane's methods for odds ratios and estimation of confidence limits.

Results

X-ray films of 632 women were reviewed as part of this study (Table I). Of these 632 women, 16 were not sexually active and 214 reported some difficulty in conceiving. Women of the walk-in and referral groups who participated in the hysterosalpingogram study, as expected, had a lower rate of pregnancies (54%) than women of the two record review groups (64% and 72%, respectively). Within the groups, there were no differences between women who had hysterosalpingograms and those who did not enter the study.

Table II presents the outcome of the hysterosalpingograms in the entire study group. Three hundred seventy-six x-ray films were reported as being abnormal (59%).

Three hundred sixty-seven of the 632 women were

not using contraception and were actively trying to become pregnant. Table III demonstrates the data relative to their success in conceiving. One hundred thirty-four women (36%) were unable to conceive for a period of 1 or more years, yet only 18% of women who did not volunteer for hysterosalpingograms reported such difficulties ($p < 0.01$). Seventy-three percent of the women who did not conceive had abnormal x-ray films. The frequency of abnormal x-ray films in the women who conceived within 1 year was essentially the same (74%). Furthermore, in women who had difficulty conceiving, the number of women with normal x-ray films (37%) was similar to the number of women with abnormal x-ray films (36%).

Of the 134 women having difficulty conceiving, 76 (57%) eventually conceived, whereas 58 (43%) were not able to achieve pregnancy during a period of 1 or more years. Seventy-two percent of the women who eventually conceived had abnormal x-ray films, where 74% of the women who did not conceive also had abnormal hysterosalpingograms. Of the group of women who had difficulty in achieving pregnancy for a period of 1 or more years, 58% with normal x-ray films and 56% with abnormal x-ray films eventually conceived. However, of the women who conceived in spite of difficul-

Fig. 2. T-shaped appearance of uterus with slight constriction of upper uterine cavity.

ties, a higher number of those with normal x-ray films (76%) conceived within 1 to 3 years compared with those with an abnormal hysterosalpingogram (45%) ($p > 0.05$). Sixty-nine percent of women who did not volunteer for the hysterosalpingographic study and had trouble conceiving did so within 1 to 3 years.

Thus it would appear that the presence of a normal or abnormal hysterosalpingogram had no influence on the ability of a woman to achieve pregnancy. Furthermore, whether a woman conceived or did not conceive did not appear to be related to the presence or absence of an abnormal x-ray film.

Next, specific hysterosalpingographic abnormalities were compared to the presence or absence of infertility. Table IV demonstrates the types of x-ray abnormalities found in 270 women. Fifty percent of the x-ray films demonstrated a T-shaped appearance of the uterus. Irregular uterine margins, uterine constriction, and a wide lower segment were also commonly observed. Table V illustrates the odds ratio for inability to conceive of these 270 women relative to specific abnormalities noted in the uterus. The presence of an abnormal uterus per se did not increase the likelihood of a woman being infertile. This is also true for the presence of a T-shaped uterus. However, the presence of a constriction of the upper uterine cavity resulted in a 2.26 times greater likelihood of a woman not being able to conceive. If a T-shaped uterus was found in association with constriction of the upper uterine cavity (Figs. 1 and 2), the odds ratio for inability to conceive was found to be 2.63. Both of these latter figures are significant ($p < 0.05$). Other abnormalities or their combinations did not have any influence on ability to conceive (not tabulated).

The data relating to evaluation of infertility were relatively scanty in the records of our study population. One hundred seven women had been evaluated for infertility. Seventy-five percent of the women with normal x-ray films and 82% of the women with abnormal x-ray films had undergone an infertility workup. Thirteen of the couples were found to have a male factor related to infertility. An equal proportion of individuals with normal and abnormal x-ray films had husbands with abnormal semen analyses. Fifty-five women were found to have some factor not related to the hysterosalpingogram that was thought to contribute to the infertility. Here again, a similar percentage of women with abnormal and normal x-ray films was present in this group. In the latter group, 32 women eventually conceived. Equal numbers with normal and abnormal x-ray films conceived.

Comment

These data suggest that the presence of an abnormal hysterosalpingogram per se is not a factor contributing to infertility. Equal numbers of women with normal and abnormal hysterosalpingograms reported difficulty conceiving. Conversely, of those women having difficulty becoming pregnant the frequency of abnormal and normal x-ray films was equal. However, when specific abnormalities found on the hysterosalpingogram were evaluated, it was noted that the presence of a constriction in the upper uterine cavity did seem to be related to infertility in the population of women studied. The presence of a T-shaped uterus in association with constriction of the upper uterine cavity also appeared to increase the chances of infertility. The report by Berger and Alpel[9] suggested that infertility of

1 to 2 years' duration in patients with uterine deformities related to diethylstilbestrol exposure carried a poor prognosis for conception. However, they did not relate the infertility to specific uterine abnormalities because of the small number of patients in their study.

There are obviously several epidemiologic defects in this review. The definition of infertility was arbitrary. All women who had tried unsuccessfully for a period of 1 or more years to conceive were included in this category. Fifty-five percent of the women who had difficulty conceiving ultimately achieved a pregnancy after 3 years (30 of 55). Of those women who did not conceive, however, it is quite possible that some of these patients may have become pregnant after the termination of this study.

Another major weakness in this review is the lack of detailed data on the infertility evaluation of the study population. It is possible that factors other than uterine constriction may have been responsible for the greater frequency of infertility in this subgroup of patients. These data were not available on the questionnaire completed by the patients.

Having concluded that the presence of a uterine constriction may be associated with an increased risk for infertility, the obvious question arises as to what can be done to help such individuals to achieve pregnancy if they are unsuccessful in doing so. Surgical correction appears totally impractical and would probably result in greater uterine deformity than was initially present. This is an approach we would not currently recommend.

Of the women who had hysterosalpingography performed, 36% reported difficulties conceiving in contrast to only 18% of women who did not volunteer for x-ray studies. This suggests some self-selection bias. It is quite possible that some of the women with infertility problems elected to have the x-ray studies performed as part of their infertility workup. However, this should not have influenced the results obtained since the data compare the frequency of x-ray abnormalities relative only to infertility in women having x-ray studies performed. The data compare frequency of infertility in individuals with abnormal hysterosalpingograms as compared with women with normal hysterosalpingograms.

Discussion

Dr. Rudi Ansbacher, Ann Arbor, Michigan. For the past 10 years, Dr. Kaufman has been interested in the genital tract changes in women exposed to diethylstilbestrol in utero. He and his associates first documented these changes in 1977,[1] and they include[2]: (1) T-shaped uterine cavity, (2) irregular contour of the uterine cavity, (3) hypoplastic uterus, (4) uterotubal constrictions, (5) cervical widening, (6) cervical-vaginal ridge, and (7) adenosis of the vaginal and cervical mucosa.

This study asked two questions: (1) Is there an association between any upper genital tract abnormalities and the ability to conceive? (2) Are specific structural changes of the upper genital tract related to infertility?

The authors pointed out the major inadequacies of their study, which include: (1) infertility was not defined specifically for their patient population; (2) the long-term follow-up of 3 years may have been inadequate; (3) there was a selection bias in the patient population studied.

Despite these inadequacies, some pertinent information can be derived from their data to answer the two questions they proposed. Women exposed to diethylstilbestrol in utero with abnormal hysterosalpingograms conceived at the same frequency as individuals who had normal x-ray films and, conversely, whether a woman conceived or did not conceive was not related to the presence or absence of an abnormal x-ray film. Therefore, in diethylstilbestrol-exposed women, it appeared that hysterosalpingograms depicting structural abnormalities of the uterine fundus played no role in the causation of infertility.

However, specific hysterosalpingographic abnormalities did appear to have a role in decreasing a woman's chance of conceiving if there was a constriction of the upper uterine cavity or if a T-shaped uterus was associated with constriction of the upper uterine cavity. There was a slightly greater than twofold likelihood of being unable to conceive in these women as compared to those with normal x-ray films.

Several questions must be asked of these authors.

They stated that a standardized x-ray review was used to ensure that the evaluations were consistent. Were the x-ray films exchanged between members of the two institutions for interpretation to ensure consistency in their interpretations?

Data relating to the evaluation of other factors associated with infertility were scanty. Were other factors that have a bearing on the success of achieving a pregnancy considered, including ovulatory dysfunction and the male factor? Why was not a properly defined control group compared with the women who were exposed to diethylstilbestrol in utero?

What was the age range of their subjects? Could this have been a factor in some of their subjects' inability to conceive? How do the authors define an inadequate hysterosalpingogram? Finally, do the structural changes, as described, affect the physiologic functions of the uterus, tubes, and cervix when compared with those of normal organs?

The authors have definitiely shown, in their defined study population, that specific hysterosalpingographic changes in diethylstilbestrol-exposed women are related to a decreased chance for fertility.

The authors are cognizant of the deficiencies in their study design, and I encourage them to further analyze their study population so that we, as clinicians, may properly counsel women who were exposed to diethylstilbestrol in utero and who desire fertility.

DR. GITA R. GIDWANI, Cleveland, Ohio. In 1977 Kaufman et al.[1] published the study that showed abnormal hysterosalpingogram changes in 40 of 60 women exposed to diethylstilbestrol in utero. Since that publication, women with diethylstilbestrol exposure in utero have walked around with a label of "infertility handicap." We at the Cleveland Clinic did not obtain routine hysterosalpingograms on our diethylstilbestrol population. However, a hysterosalpingogram was obtained if such a patient was having a hysteroscopy or laparoscopy for bleeding, dysmenorrhea, pelvic pain, or workup of infertility in the operating room.

Then came the conflicting reports of various authors regarding fertility potential among diethylstilbestrol progeny. Thus, Herbst et al. and Bibbo et al. found significantly reduced fertility rates as compared with those of control subjects whereas Barnes and Cousins found no significant change. Berger, Goldstein, and Schmidt in uncontrolled series of patients also showed a decrease in the fertility of female diethylstilbestrol patients.[2] Even though various critics questioned the validity of the data because of the individualistic presentation of the data, it was difficult to reassure a diethylstilbestrol patient with an abnormal hysterosalpingogram that she would have no "reproductive handicap."

In July, 1984, the Norfolk group, in a small series of 20 diethylstilbestrol patients with abnormal hysterosalpingograms, showed that the fertility rate in these women was no different than that of the women with no diethylstilbestrol exposure.[3] Dr. Kaufman again in this article has shown that an abnormal hysterosalpingogram per se is not a factor contributing to infertility and that an equal number of women with normal and abnormal hysterosalpingograms reported difficulty in conceiving. Conversely, of the women having difficulty getting pregnant, the frequency of abnormal and normal x-ray films was equal.

There are several weaknesses in this study, for instance, selection bias; even though the data from Mayo and Baylor were grouped together, there was a higher percentage of women volunteering for the hysterosalpingogram study who had difficulty conceiving compared with those women who did not participate in the study. Similarly, the definition of infertility was arbitrary, that is, anyone unsuccessfully attempting conception for 1 or 2 years was included and women who may have conceived after the completion of the study were excluded. There was a lack of data on the availability of other factors in the evaluation of infertility. Of course, all the above deficiencies in the epidemiology of this study have been pointed out by Kaufman et al. in their discussion.

What we would like to know is the outcome of the pregnancies in the women with abnormal hysterosalpingograms. Thus the incidence of ectopic pregnancies, spontaneous abortions, and premature deliveries has been cited to be increased in such patients by other authors. Do we have information as to how many women had viable babies?

It seems from this article that presence of constriction in the upper uterine cavity did seem to be related to infertility and the presence of a T-shaped uterus in association with constriction of the upper uterine cavity also appeared to increase the chance of infertility. The question one would like to ask is did these pregnancies reach viability? Was an operation, for instance, cerclage, or use of other drugs, such as ritodrine, necessary in these pregnancies? This is important as we know that in uteri with different defects the reproductive performance is very much related to a particular shape of the uterus.

Perhaps in the future, reproductive centers with in vitro fertilization programs could address the above questions in their series of such patients with varying shapes of uteri so that more meaningful data on the functional efficiency of such uteri can be generated. We will then as clinicians be able to predict prospectively what the degree of "reproductive handicap" is in a particular patient exposed to diethylstilbestrol in utero.

DR. EDUARD EICHNER, Cleveland, Ohio. I think the article is excellent. However, in our local area infertility includes the failure of live births, as Dr. Gidwani has stated, and the upper genital tract includes the cervix. Our biggest problem was cervical incompetence in these patients. If recognized early enough we were able to increase the positive results by cerclage, which Dr. Kaufman omitted from his study.

DR. SHAILAJA RAJ, New Orleans, Louisiana. Did the authors get any history of other drug(s) exposure (in utero) in the control subjects?

Second, do the authors have any opinion as to the cause of infertility in the group of women who had abnormality of uterus as the only cause?

DR. C. BRANDON CHENAULT, San Antonio, Texas. It was not clear to me in the discussion whether the abnormalities of the upper genital tract were changed by whether the patient was exposed to diethylstilbestrol or not. Would you clarify that for me, please?

DR. KAUFMAN (Closing). Both of the discussants very quickly noted some of the defects that we ourselves recognized in this article, but let me try to answer each of the questions as presented.

First, all the x-ray films were not reviewed by both the Mayo and Houston groups. Random x-ray films were looked at when we sent them back and forth in the mail or periodically when individuals from Baylor and Mayo met and reviewed a series of 20 to 25 x-ray films and compared their interpretations. We felt there was a relatively uniform interpretation of the x-ray films by both groups. Thus the reading of the x-ray films was fairly well standardized.

As far as the ages of the patients are concerned, I believe they varied between 19 and 32 years for individuals who had roentgenography performed.

We did not study a control population of women to look for factors causing infertility for the reason that we were simply looking to see if the presence of an abnormal x-ray film in our defined population increased the risk of infertility compared with that in women with normal x-ray films. The question we wanted to answer was whether the hysterosalpingogram would give us any hint as to the likelihood of infertility in the diethylstilbestrol-exposed woman.

The next question related to our defining an abnormal hysterosalpingogram. I believe this has been addressed in several prior publications. It was based on the appearance of the uterus: its contour, the size as estimated from the distance between the fundus and the internal os of the cervix, and the presence of various irregular defects within the uterus, such as filling defects, irregular margins, and diverticula.

The question was also raised as to how the structural changes affect the physiologic function of the uterus. I doubt very much if it is the shape of the uterus itself that affects its function. I suspect the change in the shape of the uterus is related to the functional capacity of the myometrium. There is probably a physiologic muscular dysfunction rather than a direct structural effect.

As far as the pregnancy outcome in this group of individuals is concerned, those data have also already been published. In general, the pregnancy outcome was very poor. Individuals with abnormal x-ray films had a much worse pregnancy outcome than those women with normal x-ray films. Overall, around 50% of pregnancies ended as term deliveries in women with abnormal x-ray films. Ectopic pregnancies occurred in between 8% and 10% of the individuals with abnormal x-ray films, and preterm delivery occurred in about 16% to 20% of this group of women. Even those individuals whose x-ray films were normal had a poorer pregnancy outcome than individuals who were not exposed to diethylstilbestrol, so the diethylstilbestrol exposure itself decreases the ability of these individuals to carry a pregnancy to term.

Another question was asked regarding the drugs that the patients' mothers had taken during pregnancy in addition to diethylstilbestrol. All of this material has been carefully looked into and has already been reported. The mothers had not taken any other drugs that should have been related in any way to the changes noted.

As far as whether the x-ray changes were related to the exposure to diethylstilbestrol, I do think the data would suggest that individuals who have been exposed to diethylstilbestrol in utero have a significantly higher likelihood of having uterine structural abnormalities compared with those women who have not been exposed. Obviously, unexposed individuals can occasionally show similar upper genital tract changes but with a frequency that is significantly less than in the exposed woman, probably in the range of 1% to 2%. In contrast, 40% of the diethylstilbestrol-exposed women in our record review population were found to have abnormalities.

Another question raised was related to the use of cervical cerclage in the pregnant diethylstilbestrol-exposed woman. We do not recommend that cerclage be performed except for standard indications—early dilatation and effacement of the cervix or a history of prior second-trimester abortion or early preterm delivery. In one of our previous publications, we reviewed the data on 17 diethylstilbestrol-exposed women who had cerclage performed during pregnancy. Cerclages had been done at random mainly because the patient had an abnormal x-ray film. The pregnancy outcome in this group of women was no better than that in women who did not have cerclage. Thus I would not recommend routine use of cerclage just because the woman has an abnormal x-ray film.

Primary carcinoma of the fallopian tube

Karl C. Podratz, M.D., Ph.D., Edward S. Podczaski, M.D., Thomas A. Gaffey, M.D., Peter C. O'Brien, Ph.D., Mark F. Schray, M.D., and George D. Malkasian, Jr., M.D.

Rochester, Minnesota

From 1964 through 1983, 47 patients with a mean age of 63 years underwent primary treatment of fallopian tube carcinoma. Vaginal bleeding, abdominopelvic pain or pressure, and a palpable pelvic mass (or masses) were frequent retrospective clinical associations. Survival analysis demonstrated a rapid initial rate of patient attrition with stabilization after 3 years, resulting in an overall 5-year survival rate of 41%. While independent of age, histologic grade, or original tumor size, patient longevity was significantly decreased ($p < 0.01$) by the presence of disease beyond the pelvis, neoplastic cells in the peritoneal washings, and size of residual disease. Therapy consisted of primary surgical resection, usually followed by adjunctive radiotherapy or chemotherapy. Initial sites of relapse were predominantly (88%) within the intraperitoneal cavity. The study supports definitive surgical staging and tumor reduction, as well as more selective adjuvant therapy based on surgical stage and residual tumor size and location. (Am J Obstet Gynecol 1986;154:1319-26.)

Key words: Fallopian tube carcinoma, survival analysis, staging, residual neoplasm, peritoneal cytology, relapse sites, treatment

Although the initial case of primary carcinoma of the fallopian tube was reported nearly a century ago,[1] the natural history and treatment of this disease process remain less well understood when compared with those of neoplasms of the adjacent müllerian structures. These uncertainties reflect at least in part the limited contemporary experiences at any single institution; few reports have witnessed the primary treatment of two or more patients per year during a reasonable study interval.[2-5] In addition, the variability in treatment, as well as the lack of standardized staging criteria, has resulted in suboptimal interinstitutional comparative evaluations. Our appreciation of the biologic aspects of this rare neoplasm and its responsiveness to currently available therapeutic technology will be accelerated through periodic reassessment by institutions or cooperative groups that treat larger patient populations.

We evaluated the clinicopathologic parameters of 47 patients treated for primary carcinoma of the fallopian tube and assessed the effectiveness of the treatment modalities used during the 20-year interval from 1964 through 1983.

Methods

The records of 47 patients with primary carcinoma of the fallopian tube who were treated at the Mayo Clinic between January 1, 1964, and December 31, 1983, were reviewed. The time of initiation of the present review coincided with the completion of a previous study (two decades) from our institution.[6] All lesions were retrospectively staged according to the criteria used for ovarian carcinoma, as suggested originally by Dodson et al.[7] At our institution, Stage III traditionally has been further subdivided into A and B, corresponding to residual disease ≤2 cm and residual disease >2 cm, respectively. Representative histologic sections of the primary lesions were available in all but one case and were reviewed by one of us (T. A. G.) who had no knowledge of the patient's clinical status. Both the histologic classification of Broders, as previously applied to fallopian tube carcinoma,[6] and the histologic classification suggested by Hu et al.[2] were employed for grading the neoplasms.

The following types of adjunctive radiotherapy were used: (1) intraperitoneal radioactive colloidal chromic phosphate P 32, (2) whole pelvic irradiation with or without para-aortic inclusion, and (3) whole abdominopelvic irradiation. Intraperitoneal colloidal chromic phosphate P 32 was administered at a dose of 15 mCi. The total doses, fractionation schedule, and field arrangement for both pelvic and whole abdominal irradiation were variable during the study interval. The total delivered dose for whole pelvic irradiation (with or without para-aortic treatment) ranged from 3500 to 5500 rad to the pelvis, with nine of 16 patients receiving 5000 rad or more. For patients treated with whole abdominopelvic irradiation, the whole abdomen (with partial shielding of the liver and kidneys when necessary) received from 1700 to 3500 rad, with additional doses to the pelvis and para-aortic regions in five of

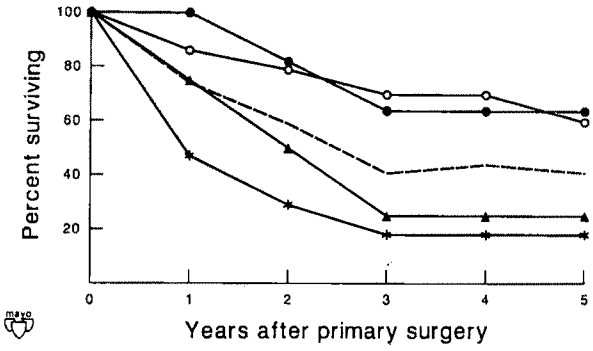

Fig. 1. Survival from time of primary operation according to tumor stage: ●——●, Stage I (n = 12); ○——○, Stage II (n = 14); *——*, Stage III (n = 17); ▲——▲, Stage IV (n = 4); - - - -, overall (n = 47).

seven patients, resulting in a total pelvic dose of 3800 to 5220 rad (four of five patients received additional doses to ≥4500 rad; one of five patients received additional doses only to 3500 rad).

Cyclophosphamide and L-phenylalanine mustard were used either alone or in the presence of progestational agents. Vincristine, cyclophosphamide, and either doxorubicin or dactinomycin were used initially (three patients) as combination therapy but more recently were replaced by cyclophosphamide and cisplatin (four patients).

To analyze the variable follow-up times (range, 15 months to 12 years) and censored survival data, the Kaplan-Meier method was used to estimate group survival. Tests of significance were based on log-rank tests for two-sample comparisons and logit-rank tests for continuous variables.

Results

The mean age of the 47 patients treated for primary carcinoma of the fallopian tube was 63 years. Evaluation of age by decade showed a peak frequency during the sixth and seventh decades; the youngest patient was 46 years old and the oldest was 84 years of age. Infertility was a common feature, with nulliparity noted in 40% (19 patients) and 57% (27 patients) having a parous status of ≤1. No relationship was noted between the associated infertility and venereal disease; only three of the 47 patients had a history of pelvic inflammatory disease, gonorrhea, and/or syphilis. Furthermore, no historical or concurrent evidence for either endometriosis or pelvic tuberculosis was found. However, in 10 patients, 12 other neoplasms were found before the tubal carcinoma was diagnosed. These included five breast, three colorectal, and two melanocytic lesions.

The most frequent presenting symptoms were vaginal bleeding (24 patients) and abdominopelvic pain or pressure (14 patients). In six patients, persistent postmenopausal bleeding eventually led to hysterectomy and the correct intraoperative diagnosis. Less frequently encountered presenting complaints were watery vaginal discharge, loss of weight, and neuropathy (three patients each). Seven patients had "other" symptoms or complaints.

Table I. Surgical stage and corresponding frequency of fallopian tube carcinoma (n = 47)

Stage	*Characteristics*	*No. of patients*
I	Carcinoma confined to fallopian tube(s)	12
A	Unilateral disease; no ascites	10
B	Bilateral disease; no ascites	0
C	Either A or B with ascites and/or neoplastic cells in peritoneal washings	2
II	Carcinoma extends beyond fallopian tube(s) but confined to pelvis	14
A	Extension to uterus and/or ovary	6
B	Extension to other pelvic organs	7
C	Either A or B with ascites and/or neoplastic cells in peritoneal washings	1
III	Carcinoma extends beyond pelvis but confined to abdominal cavity	17
A	Residual tumor size ≤2 cm	9
B	Residual tumor size >2 cm	8
IV	Carcinoma extends beyond abdominal cavity	4
Total		47

The cytologic assessment of 31 available cervical samples suggested neoplasia (Class V) in two patients (one also had a positive peritoneal cytologic study). In addition, the diagnosis of fallopian tube carcinoma was anticipated preoperatively in only three patients, two of whom had prior diagnostic procedures that identified the process. A palpable adnexal mass was present in 31 patients (66%), resulting in the clinicians generally suspecting an ovarian neoplasm. Nevertheless, while vaginal bleeding, abdominopelvic pain/pressure, and a palpable adnexal mass were frequently encountered, the complete triad occurred in only three patients (6%).

Primary surgical management consisting of staging and tumor resection was conducted at the Mayo Clinic in 36 patients (77%). The adnexal structures (either both or the remaining side) were excised in 45 patients, while hysterectomies were either previously or concomitantly performed in 41 patients. Omentectomy was accomplished in most patients, with 15% also requiring bowel resection. The distribution according to surgical stage is shown in Table I. Carcinomatous reduction to ≤1 cm was feasible in 31 patients (66%). Bilaterality was noted in four patients, with essentially equal distribution as to side in the remaining 43 patients. Involvement of the proximal third of the fallopian tube

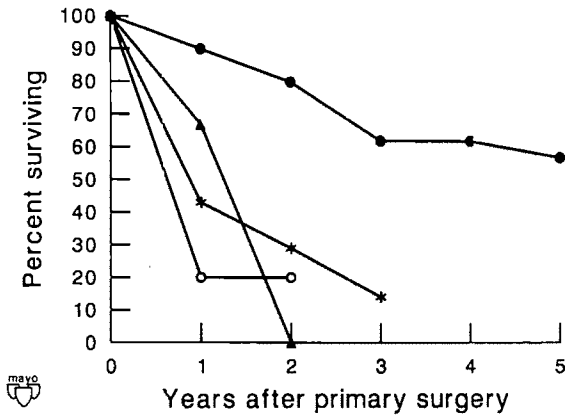

Fig. 2. Survival from time of primary operation to death from disease according to residual tumor volume: ●——●, <1 cm^3 (n = 31); ○——○, 1 to 10 cm^3 (n = 5); *——*, 10 to 100 cm^3 (n = 7); ▲——▲, >100 cm^3 (n = 3).

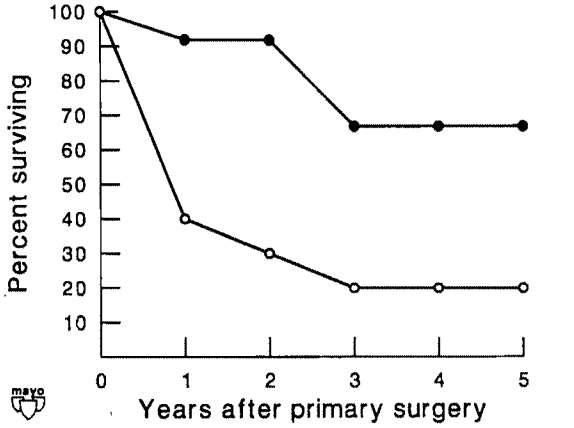

Fig. 3. Survival from time of primary operation to death from disease according to peritoneal cytologic findings: ●——●, Negative (n = 12); ○——○, positive (n = 10).

was not encountered among 37 patients eligible for site assessment. One patient had the tumor confined to the middle third only, whereas 22 had the distal third involved and 13 had the distal two thirds involved.

The overall 5-year survivorship was 41%, including a 26% attrition during the initial 12 months, with a continued decline to 44% at 3 years and stabilization thereafter (Fig. 1). While no significant differences were detected in longevity between patients having disease localized to one or both fallopian tubes (Stage I) compared with patients with disease beyond the fallopian tube but confined to the pelvis (Stage II), both groups fared substantially better ($p < 0.01$) than patients with carcinomatous involvement beyond the pelvis (Stages III and IV). Evaluation of estimated tumor volume before tumor reductive surgical procedures failed to identify a critical volume. However, survival rates for patients with residual tumor <1 cm in diameter were 80% and 57% at 2 and 5 years, respectively, and were superior ($p < 0.01$) to those of patients with larger residual tumor burdens (Fig. 2). Only three of the eligible patients in the latter subgroup were alive at 2 years.

Histologic assessment identified 43 adenocarcinomas, two squamous cell adenocarcinomas, and two mixed müllerian tumors containing adenocarcinomatous components. Both histologic grade and structural patterns were assessed. Survival at 5 years was 50%, 42%, and 39% for patients with papillary, papillary-alveolar, and alveolar-medullary patterns, respectively (p = NS). Likewise, overall 5-year survival rates were 44%, 37%, and 40% for patients with Broders' grades 1 and 2 (n = 11), 3 (n = 17), and 4 (n = 19), respectively. Individual analysis of survival according to grade within Stages I/II and III/IV also failed to demonstrate significant differences. In addition, assessment of histologic grade among patients with residual tumors of <1 cm suggested that well-differentiated lesions were associated with a more favorable survival relative to grade 3 lesions ($p = 0.03$) but not relative to grade 4 lesions (p = NS).

Peritoneal fluid or washings were obtained for cytologic analysis in 22 of 47 cases. The presence of exfoliated cells within the peritoneal cavity correlated with patient longevity (Fig. 3); survival at 2 and 5 years was 92% and 67% for patients with negative cytologic findings and 30% and 20% for those with positive cytologic findings, respectively ($p < 0.01$). As expected, intermediate survival rates of 56% and 39% were noted at 2 and 5 years for the 25 patients in whom cytologic samples were not evaluated.

Postoperative adjuvant therapy was routinely given and its impact assessed according to two subgroups (Table II): (1) patients with localized disease having complete removal with hysterectomy and bilateral salpingo-oophorectomy (Stages IA and IIA) and (2) patients with disease extending beyond the internal genitalia (Stages IC and ≥IIB). Among the 16 patients with localized disease, six died of disease (38%) at a mean time after operation of 30 months (range, 9 to 62 months). All but one of the deaths and five of six relapses (mean recurrence time, 13.5 months) occurred among the 10 patients who received no adjuvant therapy (two patients) or adjuvant therapy limited to the pelvis (three patients). However, five of the six patients subjected to more extensive therapy, with treatment of the upper abdomen by either whole abdominal irradiation or systemic cytotoxic agents in the presence or absence of intraperitoneal radioisotopes, remained relapse-free at a mean follow-up time of 39 months. The

Table II. Frequency and effectiveness of postoperative adjuvant therapy according to surgical stage

Stage	Type of adjuvant therapy*	No. of patients	Dead of disease		Progression-free survival (mo)

†One patient also received L-phenylalanine mustard.

only relapse and death in this subgroup occurred at 57 and 62 months, respectively, in a patient with Stage IIA disease who received L-phenylalanine mustard and pelvic irradiation.

In contrast, 24 of the 31 patients (77%) with disease beyond the pelvic genitalia died of disease despite adjunctive therapy. Fifteen patients had external irradiation; four of the 15 originally had presented with Stage IC, IIB, IIC, and IIIB disease and were relapse-free at 39, 140, 87, and 71 months, respectively, after receiving whole pelvic treatment either with or without para-aortic irradiation. Whole abdominopelvic irradiation was used in five patients, with two diagnosed as having Stage IIB disease (residual <1 cm) or Stage IIIA disease (residual <1 cm) and three with Stage IIIB disease, resulting in a mean time to progression of 18 months (median, 7 months), and all patients eventually died of disease. Systemic cytotoxic therapy was predominantly used as adjunctive therapy in patients with advanced stages. Initially, single alkylating agents were used either in the presence or in the absence of progestational agents; all patients so treated died within 15 months of the commencement of therapy. Combination chemotherapy subsequently replaced single-agent therapy, and longevity was marginally improved. Most recently, four patients received cyclophosphamide and cisplatin: two patients with Stages IIB and IIIB disease had progression of disease at 12 months, with death from disease occurring at 17 months in one patient and 18 months in the other, while two patients with Stage IIIA disease both were alive and free of progression at 31 months.

Progression or recurrence was experienced by 31 patients, with 61% and 84% of the relapses occurring within 12 and 24 months from the time of the primary operation, respectively; only two relapses were observed after 5 years (62 and 65 months). Among the 30 patients who died of disease were two in whom the specific cause of death was not ascertainable and four in whom the specific site of recurrence was not known. The initial sites of treatment failure were known in 24 patients, with the intraperitoneal abdominal cavity identified as the site of failure in 21 patients (88%).

Simultaneous metastastic involvement of single or multiple extra-abdominal organs also was found in six of the 24 patients, including the liver, nodes, vagina, lungs, and skin; some of these patients had involvement of more than one organ. Vertebral metastasis was the initial site of recurrence in three patients. Only one of the 24 patients survived free of disease—29 months from the time of documentation of relapse. Carcinoma at a "second-look" laparotomy was detected in a biopsy specimen of the abdominal peritoneum after the administration of 12 cycles of cyclophosphamide, vincristine, and dactinomycin for Stage IC disease. Whole abdominopelvic irradiation was given for microscopic persistence. Twenty of the remaining 23 patients died of disease within 18 months. The final three patients originally diagnosed as having Stage IIB disease and treated secondarily for recurrent disease with pelvic irradiation (operation alone originally), combination chemotherapy (operation plus whole abdominopelvic irradiation originally), and wide surgical excision (operation alone originally) died, one at 19 months, another at 26 months, and the third at 61 months after relapse.

Comment

Because the reported average annual incidence of carcinoma of the uterine tube is three per 1000 genital cancers,[6] the natural history and treatment of this disease remain less well defined than those of neoplasms

of the adjacent müllerian derivatives. The demographic features of the patients in our study were generally consistent with those from previous reports summarizing the literature.[2-4] While venereal disease, endometriosis, and tuberculosis may occasionally have been implicated in the pathogenesis of this neoplasm, historical or concurrent evidence for these processes in our review was infrequently obtained. These observations, together with the contrasting prevalence rates for pelvic inflammatory disease or endometriosis and fallopian tube carcinoma, further minimize the potential etiologic roles of these processes. However, circumstantial evidence for alterations in immunologic competence or tolerance in our and other series[8-10] is the number of patients with a prior or concomitant secondary malignant lesion.

Because carcinoma of the fallopian tube generally is manifested early by abnormal vaginal bleeding or abdominopelvic pain or pressure, confinement of disease to the pelvis at the time of diagnosis in most (55%) of our patients was therefore not unexpected.[3, 11, 12] Presumably, distention of the fallopian tube by the tumor or the resulting hydrosalpinx accounts for the frequency (30%) of associated pain. Although no involvement of the proximal portion of the tube was noted, it undoubtedly served as a conduit for blood and debris liberated by the more distal lesion and eventually was seen as abnormal vaginal bleeding in 51% of the patients. In addition, such an indirect portal to the neoplasm should imply value in cytologic sampling, which has been reported as positive in as many as 60% of evaluated patients.[3] Unfortunately, numerous reviews,[4, 7, 8, 11, 13] including the present and a previous report from our institution,[6] have been less successful in securing cytologic atypia, possibly reflecting suboptimal sampling. Despite the nonspecificity of the above signs and symptoms and the rarity of fallopian tube carcinoma, the presence of unexplained cervical or vaginal cytologic atypia, persistent unexplained abnormal vaginal bleeding or discharge after dilatation and curettage, persistent lower abdominal or pelvic pain or pressure, and the presence of an adnexal mass (66% of patients had a palpable mass in the present series) should prompt further investigation, with consideration given to diagnostic laparoscopy or laparotomy (or both) as indicated.[4]

The modes of dissemination of fallopian tube carcinoma are similar to those for ovarian cancer, occurring predominantly by cellular exfoliation with intraperitoneal spread and by lymphatic embolization to extraperitoneal sites. The process of cellular exfoliation is aided by the ready access of neoplastic cells into the coelomic cavity from their locations in the distal portion of the tube (95% in the distal one third or two thirds in our study).[8, 14] Also the sites of initial spread, including the omentum, peritoneum, intestines, and other pelvic genitalia, are similar to those described in ovarian carcinoma.[9, 13-15] These assumptions are further supported by the observation that 45% of the peritoneal washings analyzed in the present review contained neoplastic cells. In addition, a common site of metastatic infiltration at the time of documented recurrence or autopsy was the lymphatic system.[4, 9, 15] Tamimi and Figge[9] suggested that para-aortic nodal involvement is frequently encountered despite no evidence of intraperitoneal disease beyond the tube.

Because of the similarities of fallopian tube cancer to ovarian cancer, particularly in routes of initial spread and sites of subsequent recurrence, we favor the proposal of Dodson et al.,[7] employing staging criteria for fallopian tube carcinoma similar to those adopted for the ovary. However, the unusually large number of patients with disease confined to the pelvis (55%) and the similar 5-year survival rates for patients with Stages I (64%) and II (60%) disease relative to ovarian cancer suggest, at least in part, inadequate surgical staging, a fact readily apparent during the initial decade of our review. Other series with study intervals that began a decade or more before ours have noted Stages I and II disease in at least 70% of evaluable patients.[8, 11, 12] Hence the need for meticulous surgical staging as employed in ovarian cancer is apparent and should involve total abdominal hysterectomy, bilateral salpingo-oophorectomy, appendectomy, omentectomy, cytologic assessment of peritoneal washings, pelvic and para-aortic node sampling, and multiple peritoneal biopsies from high-yield areas, as dictated by the extent of gross disease.

Patient longevity was significantly decreased by the presence of disease outside the pelvis, the presence of neoplastic cells in the peritoneal washings, and the amount of residual disease at completion of the primary operation. The overall survival was 41% at 5 years, with nearly all deaths from disease occurring during the initial 36-month interval from diagnosis, undoubtedly reflecting inadequate or ineffective primary therapy. As noted above, no significant differences in 5-year survival rates were detected between patients with Stage I (64%) or II (60%) disease, but collectively this group fared better than patients with disease extending beyond the pelvis (Stage III, 18%; Stage IV, 25%). Furthermore, the results of peritoneal cytologic study seemed to have significant prognostic value, as patients who presented with negative peritoneal washings had a 3-year survival rate (67%) that was considerably more favorable than that of those patients with positive washings (20%). These observations again reinforce the necessity for inclusion of cytologic assessment in the definitive surgical staging procedure and treatment planning. Neither histologic grade nor size of the original

tumor burden seemed to have predictive significance regarding patient longevity, which is consistent with previous observations.[1, 6, 16] However, long-term survival was influenced by the size of the residual tumor after the primary operation, with a rapid attrition when residual tumor size was ≥1 cm. These results suggest that, in the overall therapeutic approach to this disease process, maximal tumor reductive efforts be made at the primary operation.

While advocates generally cite, in support of postoperative adjuvant therapy, high relapse rates among patients with localized disease and minimal salvage rates among patients with more advanced disease, the efficacy of such therapy is difficult to assess from the literature. The former, at least in part, reflects inadequate surgical staging and requires additional maturation and confirmation of treatment results after definitive intraoperative and pathologic assessment of the extent of disease before the role of adjuvant therapy in this group can be realized. In advanced disease, the various treatment modalities selected and endorsed as adjunctive therapy are generally based on limited successes in small samples and without regard to selection biases. Also the cytotoxic agents and specific dosages used, as well as the treatment fields, fractionations, and total dosages used in radiotherapy, varied considerably within the small series and among institutions. The present study is liable to similar criticisms; specifically, optimal staging was not performed during the initial decade of this review, and treatment selection frequently was determined by extent of metastatic involvement. Therefore, to reduce the impact of these deficiencies, this study population was subdivided according to the extent of disease. Patients having disease localized to the pelvic genitalia (Stages IA/B and IIA) and hence removed by surgical excision were evaluated with reference to the merits of postoperative adjuvant therapy, while patients with disease not amenable to surgical treatment alone (Stages IC and ≥IIB) were assessed for evidence that might lead to more appropriate treatment selection.

Disease localized to the pelvic genitalia (10 patients with Stage IA disease, six with Stage IIA disease) was assessed according to whether treatment was directed to the pelvis only or beyond the true pelvis. The group subjected to operation alone or supplemented with pelvic irradiation experienced a 50% relapse rate (five of 10 patients), with all patients eventually dying of disease, which is consistent with previous reports that addressed the value of adjunctive therapy in early stages.[6, 11, 14, 15] In contrast, among the patients having systemic or whole abdominal therapy or both, only one of six patients had recurrence, with the sole relapse to date occurring in the patient treated with L-phenylalanine mustard and pelvic irradiation. While limited sample size mandates cautious interpretation, these findings, as well as the predominant intra-abdominal failure patterns, support the use of postoperative adjuvant radiotherapy to the entire abdomen in this subgroup. Recently, Brown et al.[8] reported the use of postoperative whole abdominopelvic irradiation in three patients with Stage I/II disease and noted similar results, while Benedet et al.[13] also successfully treated two patients without macroscopic disease by use of intraperitoneal colloidal chromic phosphate P 32. From the available information, both the radiocolloid (chromic phosphate P 32) and external beam irradiation seem to be similarly effective in patients with Stages IA and IB and IIA disease, and both treatments merit further investigation, as has been previously suggested.[4, 8, 13]

The optimal therapy for patients with either microscopic or macroscopic residual disease beyond the pelvis remains ill-defined. Roberts and Lifshitz,[11] as well as a previous report from our institution,[6] questioned the merits of postoperative pelvic irradiation in patients with advanced disease. Consistent was the observation that only one patient with Stage III disease in the present series who received postoperative irradiation (pelvic and para-aortic) remains relapse-free, having had para-aortic nodal infiltration as the only extratubal site of metastasis. More recently, whole abdominopelvic irradiation was used in five patients who had extragenital spread, and progressive disease was noted within 7 months among three patients who had residual tumors exceeding 2 cm and at 12 and 62 months in two patients who had residual tumor of <1 cm. Recently, Brown et al.[8] reported that two of three patients with Stage III disease died within one year after whole abdominopelvic irradiation despite having no residual disease. Therefore, while the role of postoperative irradiation in the treatment of Stage IIB disease or greater of the fallopian tube appears limited, we continue to use whole abdominopelvic irradiation but only in patients with microscopic intraperitoneal disease beyond the pelvis or with minimal (<1 cm) residual disease within the pelvis or para-aortic sites.

As Yoonessi's original literature review[1] and the recent update by Brown et al.[8] indicate, experience with postoperative adjuvant chemotherapy for this tumor is likewise very limited. All patients in our series, irrespective of residual volume, who had disease beyond the genitalia and who received single alkylating agents, either in the presence or in the absence of progestational agents, died of disease within 15 months, which is consistent with the previous reports of only occasional responses, usually of short duration.[4, 5, 15] Deppe et al.[17] were the first to report the successful use of adjuvant combination chemotherapy involving cisplatin. Several subsequent reports,[5, 12, 15] including the present series

(two of four patients free of disease at 31 months) and the M. D. Anderson review (three of three patients free of disease at 9 to 33 months), suggest that regimens containing cisplatin may be of potential value in the treatment of advanced as well as recurrent fallopian tube carcinoma.

Discussion

DR. GEORGE T. SCHNEIDER, New Orleans, Louisiana. As Dr. Podratz and associates have pointed out in this well-studied series of primary tubal carcinoma, this site of cancer in the woman is still one that resists early detection and a good chance of a complete cure. This is the bad news. The only good news, I guess, is that the incidence of tubal carcinoma is still <1% of all gynecologic malignancies.

As with carcinoma elsewhere, the prognosis for fallopian tube carcinoma is determined by the anatomic extent and the grading of the disease. The authors report an overall 41% survival for 5 years, but if all of the tumor could be removed, as in Stage I and Stage II, a 64% survival rate was obtained. These figures are comparable to those of most other reported series and are quite similar to a 40% overall cure rate in our cases reviewed recently at our institution (Ochsner Foundation Hospital).

The big problem, of course, is that early detection of this lesion is infrequent and the incidence of a correct preoperative diagnosis is very low. For example, in this series of 47 cases only one was diagnosed correctly, and in the recent M. D. Anderson series, only two of 71 cases were diagnosed correctly preoperatively. This is due to the extreme rarity of fallopian tube carcinoma as compared with the more naturally suspected lesion of ovarian carcinoma.

As with endometrial and ovarian carcinoma, peritoneal cell washings should be obtained in all patients operated on with endometrial and ovarian carcinoma because favorable prognosis is directly related to negative cell findings. The addition of intraperitoneal chromic phosphate P 32 should be considered in selected cases where the tumor is resectable but cell washings are positive.

When one opens the abdomen to find an extensive, unexpected tuboovarian carcinoma, adequate excisional biopsies for immediate in vitro cultures should be obtained. There are a number of good laboratories now around the country where appropriate chemotherapeutic agents can be tested in vitro, and, therefore, a more appropriate chemotherapeutic regimen can be given.

It is disappointing that Dr. Podratz cannot give us much prognostic help with adjunctive therapy such as radiation and chemotherapy, and this is certainly true with other series. Hopefully, less toxic and more efficient chemotherapeutic agents may be developed in the future, and the use of intraperitoneal intraoperative direct radiation at the time of operation may be helpful as the technique of this radiation therapy is improved. Our surgical group in New Orleans has used it in approximately 25 cases other than pelvic cancer, mainly involving the pancreas, colon, and brain.

Finally, I would like to describe an interesting case of primary tubal carcinoma that is extremely rare; the epithelial type was squamous cell carcinoma in situ. This was in a 50-year-old patient who 10 years previously had undergone total hysterectomy and left salpingo-oophorectomy elsewhere for carcinoma in situ of the cervix. She presented with a right adnexal mass, which at operation proved to be a benign cystadenoma, but the adjacent tube removed routinely showed an epidermoid carcinoma in situ found incidentally in the pathologic specimen. The ampullary portions of the tube were free of neoplasm. We could find only two reported cases of possible primary epidermoid carcinoma of the uterine tube in the English literature. This illustrates the multicentric origin of squamous neoplasia in the müllerian system in the woman. It is interesting that 1 year after operation a vaginal vault dysplasia in this patient was detected and treated. She is

now being followed up carefully to detect any subsequent vulvo vaginal dysplastic changes.

Dr. Joseph C. Scott, Omaha, Nebraska. In patients with positive cytologic test results or those who had evidence of residual disease, did supraclavicular node biopsy play any part in deciding the future management of the patients?

Dr. Alexander W. Kennedy, Cleveland, Ohio. I would like to ask the authors two questions, one in regard to carcinosarcomas or sarcomas of the fallopian tube. We have encountered several of these recently, and I would like to know if they have encountered any in their review.

Second, did any of the patients have estrogen- or progesterone-binding protein determined?

Dr. David Hoogerland, Milwaukee, Wisconsin. Did any of the patients have periaortic lymph node involvement in the absence of any other evidence of spread?

Dr. Podratz (Closing). Dr. Schneider's sharing his interesting case again illustrated the association of secondary malignancies and possible alterations in the immune mechanisms of these patients.

With regard to Dr. Masterson's inquiries pertaining to peritoneal cytology, peritoneal fluid or washings were obtained on entry into the abdominal cavity before exploration. The pelvic viscera and the right hemidiaphragm, liver, and right upper colic gutter were washed with saline solution and the two aspirated samples were submitted for centrifugation and cytologic assessment of the resulting pellet. No attempt was made to quantitate the number of neoplastic cells.

Metastatic periaortic involvement is occasionally encountered in the absence of intra-abdominal disease and recently has been addressed in detail by Tamimi and Figge (1981). Particularly with complete agglutination of the distal end of the fallopian tube, the rich lymphatic network would predispose for this setting. Such patients with surgical Stage III disease made up a small subset in this study with one long-term survivor noted after whole pelvic and periaortic irradiation. Scalene nodes were not routinely sampled in patients with positive peritoneal washings or periaortic nodes. Our experience with this diagnostic technique has been limited to the evaluation of the patients with advanced cervical carcinoma. Likewise, intraoperative irradiation, while occasionally incorporated in the overall therapeutic approach for advanced cervical carcinoma at our institution, has not been used in the treatment schema of fallopian tube carcinoma to date.

This review was limited to adenocarcinoma of the fallopian tube but did include two cases of mixed müllerian tumors. Both contained an adenocarcinomatous component and therefore were included. In addition, a limited number of lesions were submitted for estrogen and progesterone receptor analysis. Considering the study time interval, the number of such analyses was not large enough to warrant interpretation.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Immunoglobulin G subclasses and isoimmunized pregnancy outcome

M. Mark Taslimi, M.D., Baha M. Sibai, M.D., James M. Mason, Ph.D., and John V. Dacus, M.D.

Memphis, Tennessee

Immunoglobulin G antibodies are the most frequent type of red blood cell isoantibodies. They possess the ability to traverse the placenta and may cause hemolytic disease in newborn infants. Of the four subclasses, IgG1 and IgG3 are effective at binding erythrocytes to monocyte-macrophages and therefore are potentially destructive to erythrocytes. IgG2 and IgG4 are unable to react effectively with receptor sites on phagocytic cells and so are totally inactive relative to hemolysis. IgG subclasses were identified in 22 consecutive isoimmunized antepartum patients. Fifteen patients were subsequently delivered of babies who were either affected by or susceptible to hemolytic disease of the newborn. When maternal antibodies consisted of IgG1 only, hemolytic disease of the newborn developed in four of five cases. When only IgG3 was present, each of two patients developed hemolytic disease of the newborn. In eight cases both IgG1 and IgG3 were present and all the babies were born with hemolytic disease of the newborn. Determination of IgG subclasses might prove to be a useful adjunct in evaluating isoimmunized pregnancies. However, the limited information available does not permit the use of IgG subclasses exclusive of traditional means of diagnosis and management of isoimmunized pregnancies. (Am J Obstet Gynecol 1986;154:1327-32.)

Key words: IgG subclasses, isoimmunization, hemolytic disease of newborn

The incidence of Rh isoimmunization is declining. However, isoimmunization with irregular antibodies still occurs, mostly as a result of blood transfusion,[1] and isoimmunization of pregnant women can occur as a result of antepartum or intrapartum fetomaternal hemorrhage during spontaneous or elective abortion, as a result of amniocentesis, or in the course of ectopic pregnancies.[2] As a result, hemolytic disease of the newborn is still a continuing problem.[3, 4] Immunoglobulin G antibodies are the most frequent class of red blood cell antibodies[5] and are actively transported across the placenta.[6] However, occurrence or severity of fetal and neonatal hemolysis does not correlate well with the titer of circulating maternal antibodies.[7]

Chemical structure and biologic behavior of IgG subclasses of blood group antibodies have been studied by biologists and immunologists during the past two decades.[5, 8] However, the findings have not been widely applied to the care of isoimmunized pregnant patients. IgG antibodies are divided into four subclasses based on their structural and chemical properties: IgG1, IgG2, IgG3, or IgG4. Presence of IgG antibodies on red blood cells per se does not significantly affect red blood cell survival.[5] However, antibody-coated erythrocytes, on reaching the spleen, adhere to macrophages and hemolysis occurs.[9] IgG1 and IgG3 can react with specific receptor sites on phagocytic cells and so are potentially destructive to red blood cells. IgG2 and IgG4 are totally inactive in this regard.[5, 8, 10] The purpose of the present study was to investigate the association of maternal IgG subclasses with the development of fetal and neonatal hemolysis in 22 pregnancies complicated by isoimmunization.

Material and methods

Between January 1, 1982, and December 20, 1984, we studied 22 consecutive pregnancies that had clinically significant blood group antibodies and that had been referred to the University of Tennessee Center for the Health Sciences. Maternal serum from all patients was screened for blood group antibodies according to techniques and a protocol outlined in a previous report.[11] Patients with positive indirect Coombs tests were evaluated by periodic antibody titer, serial ultrasonography, and spectrophotometric analysis of amniotic fluid bilirubin. Decisions for fetal intrauterine blood transfusion and interruption of pregnancy were made on the basis of these evaluations. IgG subclasses were identified in all patients. When serial antibody and subclass determination and amniocentesis were performed, the last test before delivery was used as the reference. Cord blood samples were collected and

NA = Not applicable, HDN = hemolytic disease of newborn; IUT = intrauterine transfusion; ND = not done.

tested as detailed previously,[11] and the type of antibody eluted from fetal erythrocytes was determined. Infants with positive cord blood antiglobulin tests were monitored by serial determination of serum bilirubin, hemoglobin-hematocrit, reticulocyte count, and other individualized tests to determine the degree of red blood cell destruction and the need for blood transfusion or exchange transfusion. Severity of hemolytic disease and the normal hematologic values for each newborn infant were determined according to standard definitions.

Spectrophotometric analysis of amniotic fluid (delta optical density at 450 nm, ΔOD_{450}) was used as the main parameter in management of these pregnancies. There were no fetal or neonatal deaths.

For maternal IgG subclassing, we used antisera specific for each of the subclasses as antiglobulin reagents in the indirect Coombs test. This agglutination test was performed in glass capillary tubes. Antisera for IgG subclassing were obtained from the Netherlands Red Cross Transfusion Service (Amsterdam). A variation of the two-layer albumin capillary test of Crawford et al.[12] was used to determine IgG subclasses. Patients' sera were used to sensitize antigen-positive cells that were then washed five times and resuspended to a final concentration of 30% to 50% cells. A capillary tube was filled one third full with subclassing antisera; then an equal volume of 30% Pentex albumin was drawn into the tube followed by an equal volume of sensitized red blood cells. The tube was inverted and embedded in clay at a 60-degree angle and observed for agglutination with a ×7 hand lens as the cells fell to the bottom. A negative control consisting of 6% albumin was run with each different sensitized cell tested. Anti-IgG4 antiserum reacts with some IgG2 molecules; so, if IgG4 is detected, no definite conclusion about the presence or absence of IgG2 can be drawn.

Results

Table I summarizes the laboratory findings and pregnancy outcome in 22 patients studied. Nine patients had anti-D antibody; one of these also had anti-Js^b. The other 13 patients had irregular antibodies, one patient having both anti-Kell and anti-Jk^a. We detected 24 antibodies in the 22 patients. The subclass composition consisted of a single IgG subclass in eight antibodies and multiple IgG subclasses in 16 antibodies. All anti-D antibodies consisted of multiple subclasses. IgG1 and/or IgG3 was present in all cases.

Direct Coombs tests of cord blood samples were negative in five cases, and cord blood was not obtained from the baby of a Kell-sensitized mother whose husband was Kell negative (Case No. 20). One patient was delivered of her infant in another institution. These seven cases were excluded from further analysis. Direct

Coombs tests of cord blood were positive in 12 cases. Three other babies were severely affected and had received intrauterine transfusions; thus cord blood direct Coombs testing was not applicable to them. These 15 patients were considered susceptible to hemolytic disease of the newborn (susceptible group).

Of the 15 patients in the susceptible group, 11 were delivered of babies with hemolytic disease of the newborn (HDN group), and four were delivered of babies with no evidence of hemolytic disease of the newborn (no HDN group). Of the HDN group, seven babies were born following spontaneous labor and had mild hemolytic disease of the newborn (cord blood hematocrit of 34% to 66%, reticulocytosis above normal range for gestational age, and/or hyperbilirubinemia), one baby was delivered at 34 weeks' gestation and required transfusion of maternal blood for hemolytic anemia (moderate hemolytic disease of the newborn), and four babies had severe hemolytic disease of the newborn and required one or more intrauterine blood transfusions and/or postnatal exchange transfusions.

The susceptible group was divided into three subgroups: patients with IgG1 only, patients with IgG1 and IgG3, and patients with IgG3 only (Table II). Subclasses of IgG2 and IgG4 were not included in the analysis of pregnancy outcome. Five patients had IgG1 only; one was delivered of a moderately affected baby, and four had no evidence of hemolytic disease of the newborn. Eight patients had both IgG1 and IgG3, and all of the infants had hemolytic disease of the newborn. Two patients had IgG3 only, and both infants had hemolytic disease of the newborn (Table II). Comparison of pregnancies with IgG1 only and pregnancies with both IgG1 and IgG3 shows significantly increased rates of hemolytic disease of the newborn in the latter group. The number of pregnancies with IgG3 only is too small for a meaningful statistical analysis.

Table II. Correlation of maternal IgG subclasses with development of hemolysis in susceptible fetuses and neonates

	Hemolytic disease of newborn	
IgG subclass	*Present*	*Absent*
IgG1 only	1 (9)	4 (11,13,14,15)
IgG1 and IgG3	8 (1,2,3,4,5,6,8,10)	0*
IgG3 only	2 (7,12)	0

Numbers in parentheses represent case numbers.
*P = 0.007, Fisher's exact test.

Comment

The five major classes of antibodies in humans are IgG, IgM, IgA, IgD, and IgE. Blood group antibodies are usually varieties of IgG, IgM, or IgA.[13] Trophoblastic receptors bind only IgG, not IgM or IgA. Maternal IgG antibodies transported across the placenta can protect against infections or be harmful to the fetus. Passage of maternal IgG to the fetus in cases of maternal Graves' disease, myasthenia gravis, and immune thrombocytopenic purpura might cause transient manifestations of the disease in the newborn infant.

IgG antibodies are the most frequent type of red blood cell antibodies produced in isoimmunized patients.[5] Trophoblasts bind and engulf IgG molecules (pinocytosis), transport them across the cell, and release the antibody on the fetal side. Active transport of IgG across the trophoblastic barrier can result in higher antibody titers on the fetal side.[6] However, the presence in the maternal circulation of IgG antibodies against antigen-bearing fetal red blood cells is not invariably associated with fetal or neonatal hemolysis.[7] Furthermore, the severity of hemolysis when it does occur does not correlate well with antibody titers in maternal circulation.[7] The results of our study agree with these earlier findings.

IgG antibodies are divided into four subclasses: IgG1 to IgG4 with differences in biologic and immunologic properties. IgG molecules have an antigen-binding fragment (Fab) and a phagocytic cell–binding fragment, or crystallizable fragment (Fc). The Fc portion is constant for each subclass of IgG.[14]

Phagocytic cells have receptor sites for the Fc portion (FcR-IgG), and only IgG1 and IgG3 have Fc portions that can react effectively with phagocytic FcR-IgG. IgG2 and IgG4 are totally inactive in this regard.[5, 8, 10] Presence of IgG antibodies on red blood cells per se does not significantly affect red blood cell survival.[5] However, antibody-coated erythrocytes are destroyed when they come in contact with and adhere to monocytes-macrophages.[9]

Binding of red blood cell–antibody complex to receptor sites on effector cells is inhibited by the presence of free IgG molecules[5]; this phenomenon is useful in isoimmunization prophylaxis. Heavily sensitized erythrocytes are destroyed whenever they come in contact with macrophages. However, in most isoimmunized patients, sensitized red blood cell sequestration and destruction are confined to the spleen where special circumstances favor adherence of sensitized red blood cells to macrophages. Because of hemoconcentration in the spleen, the amount of IgG is relatively low, and stasis occurs.[5] So, on reaching the spleen, antibody-coated erythrocytes adhere to macrophages, and cytotoxic damage, spherocyte deformation, and eventual phagocytosis of the erythrocyte occur.[9]

IgG1 is produced in larger amounts and is transported across the placenta more efficiently and much earlier than other subclasses.[15] IgG3 has a much greater affinity for phagocytic Fc receptors than does IgG1,

and so the former is more efficient in binding sensitized red blood cells to macrophages.[5] Small (and sometimes undetectable) amounts of IgG3 can cause fetal and neonatal hemolysis, while much higher titers of IgG1 might not be associated with hemolytic disease of the newborn.[5] Schanfield[16] has shown that infants born to mothers with only IgG1 have a lower hemoglobin at birth, a situation suggesting a longer period of cell destruction in utero. Infants born to mothers with IgG3 have a higher cord hemoglobin, but the rate of bilirubin rise is faster after birth. Because of intrauterine and neonatal therapeutic interventions, we have been unable to evaluate these aspects of the actions of IgG subclasses. However, our results confirm the findings of Kline[14] that IgG1 is the most predominant subclass of IgG isoantibodies produced in isoimmunized pregnancies and IgG3 is the most efficient antibody in bringing about fetal and neonatal hemolysis.

IgG1 was detected in the majority of our cases and was associated with development of hemolytic disease of the newborn in nine of 13 (69.2%) susceptible cases. IgG3 was detected less frequently but was associated with hemolytic disease of the newborn in all susceptible babies. When IgG1 was detected in the absence of IgG3, one of five neonates developed hemolytic disease of the newborn. Two patients had IgG3 only; both neonates had hemolytic disease of the newborn. Unfortunately, the limited number of patients in this series does not allow conclusive comparisons of patients with IgG1 only and IgG3 only.

In summary, biologic behavior and immunologic properties differ among IgG subclasses, and determination of subclass IgG blood group antibodies might prove to be a useful adjunct in evaluating isoimmunized pregnancies. However, the information on correlation of IgG subclasses and fetal and neonatal hemolysis is limited and should not be used exclusive of traditional means of diagnosing and managing isoimmunized pregnancies.

Discussion

DR. CHARLES M. STEDMAN, Birmingham, Alabama. Because of passage across the placenta, the IgG antibody molecule is the class of immunoglobulin of most interest to the obstetrician. Functionally, the Fc portion acts as the site of macrophage fixation and also permits active transport of the molecule by trophoblastic tissue. The Fab moiety contains the attachment sites for alloantibodies.

Once it was discovered that IgG could be divided by immunologic means into four subclasses, the hunt was on to correlate biologic activity with the type of subclass. Structurally, it is the heavy chain that provides the allotypic markers distinctive to each subclass. Taslimi and associates have chosen to address this controversial topic with a stated purpose of investigating 22 pregnancies complicated by isoimmunization. I commend the investigators on the laboratory technique selected and the use of negative controls with each specimen subjected to subclass characterization.

It is unfortunate that after reviewing the data in Table I, a total of eight patients must be removed from consideration either because the newborn infant was negative for the antigen or because a cord blood specimen was not collected. The remaining 14 patients may be separated into those with anti-D and those with irregular antibodies. Within the anti-D subset, one of nine patients demonstrated subclass 1 without 3, one patient manifested subgroup 3 without 1, and the remaining seven of nine showed a combination of subclasses 1 and 3. The irregular antibody subset contained subclass 1 without 3 in four of five patients.

My main concern with the study involves the analysis of results rather than the data collected. Table II is depicted as showing the correlation of maternal IgG subclass with the development of perinatal hemolysis.

A 2 by 2 table has been constructed when, in my opinion, there are three categories: IgG1 without IgG3, IgG3 without IgG1, and IgG1 with IgG3. When the data are rearranged, it is no longer possible to attribute any increased severity to the subclass 3 group.

The largest group in most previously reported studies has consisted of patients producing IgG1 combined with IgG3 antibodies. One inherent confounding aspect of this group is the inability to determine if there is predominantly IgG1 or IgG3 present. In a large study published earlier, Parinaud et al.[1] reported that severe hemolysis was most commonly associated with IgG1 in patients with anti-D. They even speculated that the subset of subclass 1 plus 3 might be protective when compared to subclass 1 alone. As a partial explanation for the conflicting findings in the literature, I submit that the quantity of erythrocyte-bound IgG may be as significant as the subclass identified. With the use of an enzyme-linked immunosorbent assay technique, preliminary data from our laboratory at the University of Alabama support this contention.

How does all of this translate into information useful for the clinician? As luck would have it, few erythrocyte alloantibodies are devoid of subclasses 1 or 3. As an example, Hunt et al.[2] have subclassified 86 antibodies of patients isoimmunized to 11 different antigens. Only four of 86 specimens tested failed to react with both IgG1 and IgG3. Therefore, except for the rare patient producing IgG antibody restricted to subclass 2 or 4, those of us managing patients with erythrocyte alloantibodies will continue to rely on antibody titers and more important amniotic fluid specimens for ΔOD_{450} values. Realistically, at this time, IgG subclassing remains a test looking for a clinical application.

In summary, I congratulate the authors for contributing to this area of interest, although I am unable to agree with their interpretation of the data. I look forward to a larger series from this group in the near future.

I have two questions for Dr. Taslimi. First, since the appearance of various subclasses can vary with the trimester, were the blood specimens analyzed for subclasses obtained just before delivery or several months earlier? Second, was the rate of neonatal bilirubin elevation any more rapid in newborn infants with only subclass 1 as opposed to those with subclass 1 plus 3?

2. Hunt JS, Beck ML, Hardman JT, et al. Characterization of human erythrocyte alloantibodies by IgG subclass and monocyte interaction. Am J Clin Pathol 1980;74:259.

Dr. James R. Scott, Salt Lake City, Utah. A blood test that could replace more invasive measures such as amniocentesis to monitor the severity of fetal involvement would certainly simplify the clinical management of Rh-immunized patients. Since serial anti-D titers are not sufficiently reliable for this purpose, the authors have investigated whether IgG subclass determinations might provide more useful information. This is an important issue since previous reports disagree about the relationship of IgG subclasses to the severity of hemolytic disease in the infant.[1-4] There is general agreement that IgG1 tends to cross the placenta earlier in pregnancy than IgG3, but there are conflicting data regarding which has stronger hemolytic properties.[4-6]

Unfortunately, the present series contains patients with a variety of antibodies, and there are too few patients from whom to draw definite conclusions. The clinical outcome of the infant appears to correlate best with the specificity of the antibody rather than titer or subclass. Nevertheless, the authors state that "determination of subclass IgG blood group antibodies might prove to be a useful adjunct in evaluating and managing isoimmunized pregnancies." On the basis of their data, perhaps they could explain in more detail how they propose that this should be done. It seems to me that neither the antibody titer nor the IgG subclass has sufficient predictive value to manage an individual patient. For example, Patients 8 and 10 in Table I of the article had identical anti-D titers of 1:512 and both had only subclasses IgG1 and IgG3. However, the amniotic fluid ΔOD_{450} values from one mother were in zone II and her infant was only mildly affected, while the amniotic fluid ΔOD_{450} values from the other mother were in zone III and that infant had severe hemolytic disease requiring an intrauterine transfusion. Don't these cases illustrate that only with the conventional use of amniotic fluid ΔOD_{450} values (and perhaps ultrasound findings) can differences in fetal involvement be properly evaluated and appropriately managed? Perhaps the authors could comment on this.

Finally, an interesting new developement reported recently is the possibility that large doses of intravenous immune globulin may be able to compete with Fc receptor sites to prevent the placental transfer of endogenous maternal anti-D antibody.[7] Clearly, this would be a clinically useful maneuver and warrants further investigation. It has been shown that all the IgG subclasses in exogenously administered immune globulin cross the placenta,[8] and this also has important implications for the treatment of autoimmune diseases in pregnancy and prevention or treatment of fetal infections. Therefore it is likely that the last word on antierythrocyte antibody subclasses, their relationship to hemolytic disease of the newborn, and potential ways to manipulate or prevent placental passage is not yet in. I commend the authors for renewing interest in this area and encourage them to pursue their investigations along these lines.

Dr. Sibai (Closing). I would like to thank both reviewers regarding their relevant and useful comments. I agree with them regarding the small number of patients studied in this report. However, as of September, 1985, we had studied 20 additional patients with IgG subclasses, for a total of 42 patients. Twenty-four of the 42 were considered susceptible to development of hemolytic disease of the newborn. In these 24 patients, 16 had babies with hemolytic disease of the newborn, while eight neonates did not develop hemolytic disease of the newborn even though they had a positive direct Coombs test. The IgG3 subclass was detected in 12 of 24 susceptible cases and hemolysis developed in all 12 babies. However, the IgG1 subclass was detected in 22 of 24 susceptible cases, but hemolysis developed in only 14 babies. Table I summarizes and compares neonatal outcome with the presence of either IgG3 or IgG1. There was a significant difference ($p < 0.005$) regarding the development of hemolytic disease of the newborn between cases with IgG3 present and those without IgG3.

Dr. Stedman asked about the time of determination of IgG subclasses during pregnancy. The samples were obtained during the third trimester before delivery. Serial determinations of IgG subclasses were not obtained except in two patients. However, such determinations were reported by Frankowska and Gorska[1] as well as by Parinaud et al.[2] These authors found that the pattern and titer of subclasses may change during pregnancy. In regard to his second question concerning the relationship between the IgG subclasses and the rise in neonatal bilirubin levels, the findings suggest that increased neonatal bilirubin levels are associated with the IgG3 subclass while higher cord bilirubin levels are usually associated with IgG1.[2,3]

Table I. Correlation between IgG subclasses and neonatal outcome

	*IgG3 subclass**		*IgG1 subclass†*	
	HDN	*No HDN*	*HDN*	*No HDN*
Present	12	0	14	0
Not detected	4	8	2	0

HDN = Hemolytic disease of the newborn.
*$p < 0.001$.
†NS.

Dr. Scott questioned the potential value of IgG subclasses in the management of isoimmunization considering the variable neonatal outcome with similar IgG subclass titers. He emphasized the importance of amniocentesis as the only reliable clinical method for follow-up of such pregnancies. I fully agree with his remarks. I believe that IgG subclass determinations should be considered for research purposes at present. However, they might be potentially useful in rare cases, such as in patients with isoimmunization and sickle cell disease with hepatopathy or hepatitis wherein amniotic fluid values may reflect the elevated maternal bilirubin levels.

Experience with intrauterine insemination for cervical factor and oligospermia

Magdalen E. Hull, M.D., David M. Magyar, D.O., Jaime M. Vasquez, M.D., Maria F. Hayes, M.D., and Kamran S. Moghissi, M.D.

Detroit, Michigan

In the past 100 years, interest in intrauterine insemination for cervical factor has waxed and waned. Recently the advent of in vitro fertilization, with improved methods of sperm washing and preparation, has revived interest in intrauterine insemination as a modality for the treatment of infertility. Twenty-seven couples with infertility resulting from cervical factor and/or oligospermia were entered into our intrauterine insemination protocol. A total of 107 intrauterine inseminations were performed in 85 menstrual cycles. Nineteen couples with a cervical factor as the major factor in their infertility experienced three pregnancies (16%). The remaining eight couples who had oligospermia with or without cervical factor produced no pregnancies. No major complications occurred from this procedure. In view of the low pregnancy rate experienced in this study, we must seriously question the value of intrauterine insemination in the treatment of cervical factors and/or oligospermia. (AM J OBSTET GYNECOL 1986;154:1333-8.)

Key words: Cervical factor, intrauterine insemination, oligospermia

Intrauterine insemination has been a subject of controversy for the past 100 years.[1] Recently with the development of in vitro fertilization and accompanying methods of sperm washing, intrauterine insemination is being increasingly used to treat infertility almost irrespective of its apparent cause. Thus indications for intrauterine insemination have been extremely varied, vague, inconsistently applied, and oftentimes empiric. Reported pregnancy rates have varied from as low as 3% to as high as 75%. For these reasons this study was performed. Although it is beyond the scope of this paper to consider all possible indications for intrauterine insemination, it is our purpose in this study to evaluate the merits of intrauterine insemination for the treatment of couples with infertility resulting from cervical factors, with or without accompanying oligospermia.

Material and methods

Patient selection. Couples with other infertility factors that were untreated were eliminated from the study. A careful history was obtained and physical examinations performed for all couples. Infertility evaluation for all couples included a hysterosalpingogram, multiple semen analyses, basal body temperature charting, and luteal phase endometrial biopsies. Laparoscopy and tubal dye perfusion were performed when indicated.

Cervical infertility was diagnosed initially by the performance of at least two well-timed postcoital tests. Cervical mucus was scored according to the scheme recommended by the World Health Organization.[2] Additional tests performed to confirm abnormalities of sperm-cervical mucus interaction included hyperstimulation with estrogen, in vitro sperm-cervical mucus penetration tests, cross-hostility tests, and insemination testing. The presence of sperm antibodies were excluded by performing sperm immobilization and sperm-agglutinating antibody testing in sera, cervical mucus, and seminal fluid of the couple.

Oligospermia was diagnosed after two semen analyses, performed at least 2 weeks apart, were evaluated according to the criteria recommended by the World Health Organization.[3] Those men who had a total sperm count below 120 million or less than 20 million sperm per milliliter of seminal fluid were considered oligospermic.

Sperm preparation. Couples were asked to abstain from intercourse for at least 48 hours before specimen collection. Semen samples were obtained by masturbation and allowed to liquefy for 30 minutes. Sperm were counted on a Neubauer ruled hemocytometer. Motility and morphology were determined according to the guidelines set by the World Health Organization Standard for Rating Sperm Morphology.[3]

Ham's F10 media was prepared in advance and adjusted for pH and osmolarity. Sera from the wife was prepared in advance in 1 ml aliquots, detoxified at 56° C for 30 minutes, and stored at −70° C until in-

semination. On the day of insemination the 1 ml aliquots were thawed to 37° C and a 7.5% solution containing the wife's serum and Ham's F10 media was prepared before sperm washing.

Semen samples were admixed in equal volumes with the 7.5% serum and Ham's F10 solution and centrifuged at 427 g for 7 minutes. The supernatant was discarded, and the pellet was resuspended with 2 ml of media and recentrifuged at 427 g for 7 minutes. The remaining pellet was then resuspended in 1 ml of media and incubated for 30 minutes at 37° C in 5% CO_2. During the incubation period the nonmotile sperm are allowed to settle out while the motile sperm remain in the supernatant. The supernatant was then removed and reassessed for sperm count, motility, and morphology.

Insemination, timing, and technique. Couples were inseminated at the time of ovulation as determined by basal body temperature and rapid urinary LH assay (Ovustick, Monoclonal Antibodies, Inc., California) performed on a daily basis beginning on cycle day 10.

Intrauterne insemination was performed under sterile conditions with a tuberculin syringe filled with sperm suspension attached to an 18-gauge angiocatheter 2 inches in length.

Statistical analysis. Means and standard errors of the means as well as standard deviations were calculated. Differences between normal and oligospermic men were evaluated by paired *t* test and correlated by computer analysis.

Results

Twenty-seven couples either with primary or secondary infertility underwent intrauterine insemination. The mean (±SD) age of the women who participated was 31.96 ± 0.80 years. The duration of infertility was 4.64 ± 0.72 years. Five of the women had previous conization or cryotherapy of the cervix for dysplasia, and one had a history of exposure to diethylstilbestrol in utero. Eight men were thought to have idiopathic oligospermia unresponsive to usual therapeutic modalities.

A total of 107 inseminations were performed in 85 cycles with a total of 3.12 cycles per couple as seen in Table I. Of the twenty-seven couples inseminated, 19 patients had only a cervical factor. No pregnancies occurred in the four couples with oligospermia or in the four couples with oligospermia as well as cervical factor.

Occasional minor complications were noted such as spotting in three cycles and mild discomfort after insemination in two patients. No major complications were observed.

Overall, as shown in Table II, there is a statistically significant difference, as expected, in ejaculate volume before and after washing ($p < 0.00$_). The observed sperm count is significantly different in the prewash and postwash specimens, in that the mean sperm count fell from 85.21 million per milliliter to 66.47 million per milliliter ($p < 0.05$) following the washing procedure. In addition, sperm motility was observed to be less after washing—48.79% as compared to a prewash value of 50.7%—but was not statistically significant. The percentage of sperm demonstrating normal morphology was found to increase from 58.65% to 60.58% ($p < 0.05$) in the postwash specimen.

Differences were noted in the prewash and postwash specimens of normal versus oligospermic men. As shown in Table III, there were differences in volume between raw ejaculates and washed sperm regardless of the sperm counts before washing. Subjecting sperm

from normal men to washing does not seem to change the recovered amount of sperm significantly. However, those men with oligospermia had significantly fewer sperm recovered after sperm washing compared to their prewash counts. Also the overall mean percentage of motile sperm changed significantly in the postwash specimens of the oligospermic men from 49.7% to 46.5%. The mean percentage of sperm demonstrating normal morphology increased postwash in normal men and decreased postwash in oligospermic men, but neither change was statistically significant.

We also examined total sperm counts (multiplying volume by count per milliliter) in both normal and oligospermic men. As expected, the total count decreased after sperm washing. Other aspects such as motility and morphology when evaluated (by multiplying percent of motility and of morphology by total count) were found to decrease.

Comment

In the past, intrauterine insemination has often been described as disadvantageous and even dangerous.[1] Intrauterine insemination was initially performed with use of the entire ejaculate, and comptemporary reports listed complications such as anaphylaxis and pelvic infection. It was later recognized that the seminal plasma was a possible vehicle for infection, and the procedure was abandoned. The discovery of prostaglandins in seminal plasma along with the popularization of split ejaculates for artifical insemination by the husband led to a revival of intrauterine insemination.[1-6] The use of small volumes and split ejaculates has lessened the incidence of pain and complications associated with intrauterine insemination.[7-9] The use of sperm washing and aseptic techniques, in our hands, reduced the complications to mild uterine cramping and occasional vaginal spotting.

The results of our study, however, do not show any significant improvement in the rate of pregnancy by use of washed sperm and intrauterine insemination techniques. In fact, our results are no better than that obtained in our previous reported experience with intracervical insemination techniques and unwashed husband sperm.[10] We believe that this is due to the failure of washing techniques to improve sperm quality in any marked way. Instead of improving the quality of inseminated sperm, our technique appeared to actually decrease the number of sperm inseminated without any improvement in motility as has been substantiated by others.[11]

When the prewash and postwash specimens were compared in relation to normal and oligospermic men, differences became apparent. Postwash sperm counts and motility actually decreased when compared to prewash specimens in the oligospermic group. This is in contrast to data reported earlier by others.[12] However, the sperm count and motility of the group of normal men did not change significantly. Therefore, we believe it is the overall quality of sperm before sperm washing and not the technique of sperm washing that should be held accountable for the lack of improvement in quality of postwash specimens.

In this study we were very careful to limit the performance of intrauterine insemination to couples in whom there actually existed an indication for this procedure. The use of intrauterine insemination and sperm washing techniques in this group of patients with infertility resulting from cervical factors and/or oligospermia did not result in an increased rate of pregnancy over other conventional methods of therapy.[10] We believe that this is the probable result of the inability of our sperm washing technique to functionally improve the quality of postwash sperm either in normal men or especially in oligospermic men. Results obtained by Confino et al.,[13] in a recent study using intrauterine insemination techniques, were similar. Their overall pregnancy rate for all couples was 30%, but none of the couples with oligospermic men achieved pregnancy. Their most encouraging results came in the group of patients with hostile cervical mucus in which the preg-

nancy rate was 68%.[13] Similarly, couples with cervical factors conceived at a rate of 75% per patient following intrauterine insemination, while couples, overall, demonstrated a pregnancy rate of 28% per patient in a recent report by Kirsch et al.[14]

Thus it would seem that intrauterine insemination may yield extremely high rates of pregnancy in couples with cervical factors including hostile cervical mucus. Although the pregnancy rate in couples with cervical factor only in the present study was merely 16%, all couples had previously exhausted other more conventional treatment for cervical factors before proceeding to intrauterine insemination. It is not clear at this time whether couples in other studies were similarly treated before undergoing intrauterine insemination.

Intrauterine insemination with use of sperm washing techniques requires a sophisticated laboratory with personnel available on a daily basis. Sperm preparation is time consuming and more expensive than conventional insemination techniques with use of intracervical or intravaginal sperm insemination. Until further, more extensive and controlled studies can be performed, we are concerned that intrauterine insemination may offer no added benefit for the treatment of infertility related to oligospermia. Further study may more clearly define its role in the treatment of cervical factors that are not responsive initially to more conventional methods of treatment.

Discussion

DR. DENNIS J. LUTZ, Minot, North Dakota. Intrauterine insemination remains a subject of controversy despite a quarter-century of increasing efforts to evaluate the merits of the technique. Inconsistent and occasionally contradictory reports on the successful treatment of infertile couples with intrauterine insemination have not adequately resolved this controversy. The authors have selected a relatively small subset of couples with infertility caused by cervical factors, with or without accompanying oligospermia, and attempted to assess the merits of intrauterine insemination by means of washed homologous semen. Several aspects of the study design require clarification.

The selection of couples for this study required cervical factor infertility based on the diagnosis of repeated "poor" postcoital test results, implying that infertility was due to abnormal sperm-mucous penetration.[1] Nevertheless, the average age of each woman was 32 years and the average duration of infertility approximately 5 years. This would suggest a study bias toward older couples who may have other unexplained infertility factors in addition to the cervical and/or oligospermia factors. A more detailed fertility profile of these couples, including primary and secondary infertility data, might be elucidating. No mention is made of hormonal therapy for cervical factor infertility in this same study cohort, either before, in conjunction with, or after attempted intrauterine insemination cycles.

Furthermore, only an average of three cycles of intrauterine insemination per couple were performed. Is that an adequate trial of the technique for this particular subset of extremely refractory infertility patients? In an earlier report for homologous artificial insemination by means of the split ejaculate technique, Moghissi et al.[2] required a prescribed course of six or more attempts.

Obviously the study cohort is small, particularly for these couples with oligospermia, with or without cervical factor; therefore, results for these two groups cannot be interpreted on the basis of intrauterine insemination techniques alone. Not only would a much larger study group be required, but also a control group using intrauterine insemination with washed donor semen would be useful. In any event, the use of washed semen and intrauterine insemination technique does not seem to improve pregnancy results for any group now or previously studied by the authors. Indeed, Glass and Ericsson[9] have concluded that even the best sperm from

a poor specimen may have intrinsic defects that interfere with their ability to fertilize.[3]

This report may dampen the enthusiasm of proponents of intrauterine insemination as a technique for bypassing cervical factor infertility and of sperm washing as a panacea for circumventing oligospermia. Our own data using unwashed, split ejaculate intrauterine insemination for cervical factor infertility is no more encouraging. Indeed the three pregnancies (16%) among the 19 couples diagnosed as pure cervical factor may represent either dismal or truly excellent results within this refractory infertile cohort. Unfortunately, that judgment cannot be determined from the data presented today.

DR. ASGHAR AFSARI, West Bloomfield, Michigan. Artificial insemination was introduced in the clinical field, as a means to promote conception, by John Hunter in 1790.[1] Approximately 200 years later, it still remains a viable tool for infertility treatment. However, in some instances the value of this procedure has also been a myth. Widespread use of this procedure, with or without good clinical indication and technique, as well as imprecise timing and inadequate frequency of the procedure per cycle, verifies this.

This paper addresses itself to the treatment of couples with sperm and/or cervical infertility with the use of washed sperm and intrauterine insemination. I would like to comment on these two distinct areas of interest, as well as patient selection and methodology.

First, while oligozoospermia, asthenozoospermia, or combination of both continues to be by far the most frequent abnormalities encountered, varicocele is considered to be the most frequent etiologic factor. I am interested in learning whether safeguards were taken by the authors to rule out this condition. Although it is simple to detect a varicocele, occasionally the detection of an occult varicocele is quite enigmatic.

So far as the treatment for sperm factor is concerned, newer and more contemporary means are advised. Administration of gonadotropins to subfertile men is reported to have achieved a 40% improvement.[2]

It has been shown[3] that intrauterine insemination leads to a 25% increase in peritoneal recovery of the sperm, when compared to intracervical insemination. Now the ever-popular form of intrauterine insemination, with the use of capacitated sperm, for the purpose of selection of more motile sperm, has been shown to be a superior method. The technique of sperm washing as described by the authors of this paper, shows that the quality of the sperm not only was improved but surprisingly had a deleterious effect, resulting in an overall pregnancy rate of only 11%. This is contrary to the work of Balmaceda et al.,[4] who achieved an overall improvement of sperm motility from 51.7% to 85% and obtained a 50% pregnancy rate. It is also interesting to note that, nevertheless, a 14% pregnancy rate is expected to occur spontaneously after discontinuation of a regimen of homologous insemination in a group of subfertile men.[5]

Second, various courses of treatment are advocated when cervical infertility is encountered. These include low-dose estrogen stimulation, antibiotic therapy, cryotherapy of the cervix, donor cervical mucus, and last, intrauterine insemination. An encouraging result of 68% to 75% pregnancy rates is at hand with the use of washed sperm for intrauterine insemination.

Dr. Hull and her colleagues denote that all couples had previously exhausted other conventional treatment for cervical infertility before proceeding with intrauterine insemination. I wonder if administration of human menopausal gonadotropin plus human chorionic gonadotropin with or without daily high doses of estrogen also had been tried. The above therapy is reported to render a better success rate in achieving pregnancy.[6, 7] Bearing in mind that artificial insemination causes an anxiety reaction in couples, resulting in temporary oligoanovulation, this method of treatment for the most part may override the wife's emotional upheaval, caused by their infertility problems in general, but more specifically by the need for artificial insemination.

Third, the methodology designed by the authors of this paper deserves more comment. They have acknowledged that laparoscopy was performed when it was indicated. Does this mean that it was not performed on all patients? If this is the case, I believe that the extent of couple evaluation to rule out any pelvic pathologic conditions was incomplete. In comparison, Kirsch et al. performed laparoscopy on all patients before the intrauterine insemination. They were then able to demonstrate the pregnancy rate of 75% in couples with cervical infertility and only 5% in the group with history of endometriosis. This phenomenon is more than likely due to an altered prostaglandin secretion, an inherent type of problem with endometriosis. The low pregnancy rate of 16%, reported through this paper, may then be attributed to the poor selection of patients and also to failure to proceed with screening laparoscopy on all patients who entered the protocol. I wonder whether any of the patients who failed to conceive were subsequently given a diagnostic laparoscopy, and whether any organic pelvic pathologic condition or endometriosis was discovered.

In addition to above comments, I agree with the authors that their method of sperm washing is insufficient to produce a better quality sperm. My concern involves the use of the wife's serum as part of the washing medium and the use of supernatant alone, after the second wash, for the final specimen for intrauterine insemination. By modifying the two above areas, the authors

may find a higher rate of pregnancy as well as a simpler, faster, and consequently more gratifying technique.

Dr. James Miller, Seattle, Washington. You stated that you "used laparoscopy when indicated." I would like to know when laparoscopy is not indicated in an infertility workup.

With regard to your timing, basal body temperatures are notoriously inaccurate, and the luteinizing hormone kits are not all that good either. Recently in Seattle we compared luteinizing hormone kits to serum luteinizing hormone determinations and found they were accurate only 75% of the time.

I agree with the discussants that in 30-year-olds three tries are hardly adequate to draw a conclusion.

Dr. Karol J. Chacho, Chicago, Illinois. In light of the normal attrition in the number of sperm that successfully migrate from the cervix into the uterine cavity, I wonder why you did not select a technique that would have decreased the concentration but perhaps increased the percent motility of your specimen.

Also, what is your feeling about depositing that concentration of sperm into the uterine cavity, and did you look at sperm antibodies after the procedures compared to before the procedures to see where there was any difference?

Dr. Hull (Closing). The diagnosis of cervical factor was indeed made after two well-timed postcoital tests and after poor results were obtained through in vitro sperm-cervical mucus penetration tests and cross-hostility tests, and there was failure to respond to high doses of ethinyl estradiol. The oldest patient we encountered was about 41 years old. The average age was 31.9 ± 4.2 years.

Cervical factor was treated hormonally before institution of insemination therapy, that is, with high-dose estrogens, either Premarin (1.25 mg) or ethinyl estradiol (20 mg) daily for a total of 14 days, and then withdrawal with Provera. If they had responded with production of cervical mucus, they were not included in this study. If they had not, they then proceeded on to intrauterine insemination.

Regarding the question of whether three or more cycles is adequate, I do agree that this is not. We are continuing to study this further, and thus this is a preliminary report of our data.

Dr. Afsari raised the question about the use of estrogen therapy in conjunction with Pergonal and human chorionic gonadotropin. We found that if the patients were not responsive to high doses of ethinyl estradiol or Premarin, we then proceeded to do sperm washing along with intrauterine insemination because we felt that they were more unlikely to respond to Pergonal (human menopausal gonadotropin). Indeed, some patients in the group did go on to Pergonal therapy and did not produce mucus during those cycles and also required intrauterine insemination.

A question was raised whether or not all patients had laparoscopy to rule out other factors such as endometriosis. All patients did not have laparoscopy, and I agree that this may be part of the fault of the study; but they did demonstrate patency of the tubes. Twenty patients had laparoscopy before intrauterine insemination, and 18 were not found to have endometriosis. Two had minimal disease. The remaining seven patients did not have a laparoscopy.

Dr. Miller raised the question that the luteinizing hormone kits were unreliable in his experience. We have not found any problems with luteinizing hormone kits. We have used them in conjunction with luteinizing hormone assays in our in vitro fertilization program and have not found a problem with them.

Concerning the question about postwash formation of antibodies, the reason we used a 7.5% solution of the wife's sera was that we wished not to stimulate any antibody formation, and we used the woman's own proteins. I do know of one study that used intrauterine insemination in patients with a history of antisperm antibodies, and the titers were elevated significantly after several inseminations. However, in cases known to have cervical factor without antisperm antibodies, the answer is unknown.

An analysis of the factors involved in the colposcopic evaluation of 2194 patients with abnormal Papanicolaou smears

David W. Wetrich, M.D.
Iowa City, Iowa

Two thousand one hundred ninety-four patients with abnormal Papanicolaou smears were evaluated by colposcopy without endocervical curettage in the initial part of the series but with routine endocervical curettage in the latter part. Forty-two cases of microinvasion-invasion were all accurately diagnosed with no postcryotherapy occurrence of these lesions. Evaluation of the Papanicolaou smear, colposcopic biopsy specimens, squamocolumnar junction location, and use of surgical removal for severe dysplasia–carcinoma in situ appeared to be most important in the successful outcome. Endocervical curettage played a minor role. Multiple positive cross correlations between Papanicolaou smear severity, colposcopic biopsy specimen severity, squamocolumnar junction nonvisualization, positive results of endocervical curettage, increased lesion size, increased age, and microinvasion-invasion occurrence were all demonstrated.
(AM J OBSTET GYNECOL 1986;154:1339-49.)

Key words: Colposcopy, Papanicolaou smears, cervical dysplasia

This report attempts to analyze the contribution of several variables to the successful use of colposcopic triage as performed at the colposcopy clinic at University Hospitals from its inception in 1971 through 1983. The variables analyzed include the degree of Papanicolaou smear abnormality, histologic results of colposcopic biopsy, squamocolumnar junction location, endocervical curettage, lesion size, and patient age.

Material and methods

A total of 2194 patients with abnormal Papanicolaou smears were evaluated by colposcopy by means of standard techniques in a resident clinic supervised by myself. From 1971 to 1976, endocervical curettage was rarely used, wereas it was almost always used from 1977 to 1983.

Results

Identification of patients with microinvasion or invasion was a major objective with 42 patients having one of these diagnoses. Before 1977, there were eight patients with invasive carcinoma and 18 with microinvasion, and after 1977, there were 11 patients with invasive carcinoma and five patients with microinvasion for a total of 19 patients with invasive carcinoma and 23 patients with microinvasion. In all instances these patients were identified as a result of the initial evaluation steps, and no diagnoses were delayed by inappropriate cryotherapy or advice to have a repeat Papanicolaou smear or colposcopy after a waiting period. No patients developed these lesions after cryotherapy. The successful accomplishment of the colposcopic evaluation was dependent on the analysis of a number of variables, which included Papanicolaou smear severity, pathologic results of colposcopic biopsy, squamocolumnar junction visualization, endocervical curettage findings, lesion size, and patient age. The data from our series regarding these variables will be reviewed.

The degree of Papanicolaou smear abnormality is correlated with the severity of the subsequent colposcopic biopsy results. This is displayed in Table I. It can be noted that there was 85.9% agreement between Papanicolaou smear and colposcopic biopsy results. A total of 4.5% had a Papanicolaou smear result much more severe than the colposcopic biopsy result and 9.6% had a colposcopic biopsy result much more severe than the Papanicolaou smear. The 9.6% discrepancy indicates the false negative problem of Papanicolaou smears. As all the patients had abnormal Papanicolaou smears before referral it is of interest that 27% had normal Papanicolaou smears at the colposcopy clinic. Of those with normal Papanicolaou smears at colposcopy 43% had some degree of dysplasia on colposcopic biopsy. This demonstrates that after an abnormal Papanicolaou smear and with no intervening therapy a normal Papanicolaou smear has a high liklihood of being false negative. Comparing the colposcopic biopsy diagnosis with the colposcopic Papanicolaou smear revealed that 16.3% of all patients with dysplasia–carcinoma in situ of any degree on colposcopic biopsy had normal colposcopic Papanicolaou smears. Of those with mild dys-

Entire series	2194	23	19	1.9

plasia on biopsy, 31.6% had negative Papanicolaou smears; of those with moderate dysplasia on biopsy, 15.0% had negative Papanicolaou smears; of those with severe dysplasia on biopsy, 8.3% had negative Papanicolaou smears; and of those with carcinoma in situ on biopsy, 6.2% had negative Papanicolaou smears. These figures demonstrate the false negative problem of Papanicolaou smears and also that the more advanced lesions are less likely to result in negative Papanicolaou smears.

Of interest also is the outcome of patients with a Papanicolaou smear that was significantly more severe than the colposcopic biopsy result. There were 42 patients with severe dysplasia or worse on Papanicolaou smear but with colposcopic biopsy results that were much less severe (greater than one grade). Thirty-three of these patients had subsequent cone biopsy and/or hysterectomy and the subsequent pathologic results were normal in five, mild dysplasia in five, moderate dysplasia in five, severe dysplasia in 11, carcinoma in situ in five, microinvasion in one, and invasion in one. These data demonstrate that the colposcopic biopsy also has a false negative problem that may be revealed by the Papanicolaou smear being significantly worse. Conversely the Papanicolaou smear has only a minor false positive problem.

The degree of Papanicolaou smear abnormality is also correlated with the likelihood of coexisting microinvasion or invasion and this is demonstrated in Table II. Even milder Papanicolaou smear abnormalities may be associated with advanced disease but with increasing Papanicolaou smear severity there is a strong correlation with the likelihood of microinvasion-invasion.

Colposcopic biopsy pathologic results are correlated with the ultimate pathologic diagnosis on cone biopsy or hysterectomy as displayed in Table III. There are discrepancies where the colposcopic biopsy underestimates the severity of the lesion and these discrepancies are most likely to occur when the squamocolumnar junction is not visualized or the endocervical curettage is positive. Significant discrepancies were found in 8.8%

Table III. Colposcopic biopsy pathologic results versus worst pathologic result on cone biopsy or hysterectomy in 500 patients, 1971 to 1983

Colposcopic biopsy pathologic result	*Cone or hysterectomy pathologic result*						
	Normal	*Mild dysplasia*	*Moderate dysplasia*	*Severe dysplasia*	*Carcinoma in situ*	*Microinvasion*	*Invasion*
Normal	14	5	4	6	1	–	–
Mild dysplasia	7	14	10	8	2	2	–
Moderate dysplasia	6	24	29	19	8	–	–
Severe dysplasia	17	26	36	60	30	2	–
Carcinoma in situ	8	8	14	22	89	8	2
Microinvasion	1	1	–	–	7	4	2
Invasion	–	–	–	–	–	–	4

with colposcopic biopsy results less severe by two gradations than subsequent pathologic findings in the 1971 to 1983 series of 500 patients who underwent cone biopsy and/or hysterectomy. Of these 44 patients 30 or 68% had nonvisualization of the squamocolumnar junction. In the 1977 to 1983 series where endocervical curettage was done, 17 of 264 patients had more severe abnormality at conization or hysterectomy than at colposcopic biopsy and 10 of 17 or 59% had a positive result of endocervical curettage. Cross correlation of squamocolumnar junction evaluation and endocervical curettage results in these discrepant cases from 1977 to 1983 is displayed in Table IV. In 15 of 17 discrepant cases either the squamocolumnar junction was not visualized or the endocervical curettage result was positive. The other clue to colposcopic biopsy discrepancies is the occurrence of a Papanicolaou smear with much worse findings, as mentioned earlier.

Visualization of the squamocolumnar junction is one of the two methods used to identify those patients with endocervical disease. The percentage of patients with visualization of the squamocolumnar junction was 80.3% before 1977 and 74.4% after 1977 or 77% for the entire series. Review of colposcopic biopsy diagnosis versus squamocolumnar junction visualization reveals that when the squamocolumnar junction was seen 9% of patients had carcinoma in situ, microinvasion, or invasion. When the squamocolumnar junction was not visualized, 21% had these more severe lesions. Of 219 patients with these more severe lesions, 41% had nonvisualization of the squamocolumnar junction and in 49% the squamocolumnar junction was seen. Visualization of the squamocolumnar junction in those patients with microinvasion and invasion is displayed in Tables IV, V, and VI. The data reveal that the squamocolumnar junction is more often not visualized in the more severe lesions and is particularly unlikely to be seen in patients with invasion.

Endocervical curettage is the other index of the presence of endocervical disease. This procedure was rarely used in our series before 1977 but since has been used routinely. In the 957 patients since 1977 who had an endocervical curettage, the endocervical curettage result showed moderate dysplasia or worse in 8.6%, mild dysplasia in 3.7%, and dysplasia unspecified in 1.7%. These 14% of patients are subsequently referred to as having positive endocervical curettage results. A total of 14.4% had insufficient tissue and 70% had benign tissue; these 84% of patients are subsequently referred to as having negative endocervical curettage results. Comparing the endocervical curettage result to the severity of the abnormality on colposcopic biopsy reveals that when the result was positive 24% of the patients had carcinoma in situ, microinvasion, or invasion and when the result was negative 6% of patients had these more severe lesions. Of the 79 patients who had these more severe lesions on colposcopic biopsy and had an endocervical curettage, 39% had a positive result and 61% had a negative result. The correlations of endocervical curettage results with microinvasion-invasion are displayed in Tables IV, V, and VI. It is obvious that the more severe lesions have a higher incidence of positive endocervical curettage results but also of note is that of 18 patients with microinvasion or invasion who underwent endocervical curettage five had a negative result. The endocervical curettage in addition to detecting endocervical disease may also yield tissue that may give a histologic diagnosis that is more severe than that found on colposcopic biopsy. In the total 1977 to 1983 series there were 35 patients with mild dysplasia on endocervical curettage and 88 patients with moderate dysplasia or worse. Of the 88 patients with mod-

erate dysplasia or worse on endocervical curettage, 22 were patients with the squamocolumnar junction seen. Of these 22 patients the endocervical curettage diagnosis was worse than the Papanicolaou smear or colposcopic biopsy diagnosis in four of 22 and much worse (greater than one grade) in two of 22. Six patients with a final diagnosis of microinvasion or invasion had the squamocolumnar junction seen and none had an endocervical curettage done. Among the 66 patients with moderate dysplasia or worse on endocervical curettage with the squamocolumnar junction not seen, the endocervical curettage result was worse than the Papanicolaou smear or colposcopic biopsy result in seven of 66 and much worse (greater than one grade) in two of 66. Thirty patients with microinvasion or invasion had the squamocolumnar junction not seen; an endocervical curettage was done in 17 and results were positive in 13. In five of these 13 the endocervical curettage showed microinvasion or invasion but in all five cases the colposcopic biopsy also showed microinvasion or invasion. Thus overall among 1042 patients who had an endocervical curettage done in only four did the endocervical curettage yield tissue that was much worse (greater than one grade) histologically than that found on colposcopic biopsy. Also of note is the absence of microinvasion or invasion diagnosed on the endocervical curettage and not on the colposcopic biopsy. On the basis of our data it appears that the endocervical curettage will very infrequently yield a more severe histologic diagnosis that will change management significantly. The endocervical curettage may more often modify management by simply identifying endocervical disease.

Visualization of the squamocolumnar junction and endocervical curettage are both used to identify the presence of endocervical disease and should correlate closely with each other. In those patients who had both endocervical curettage and visualization of the squamocolumnar junction in the 1977 to 1983 series these cross correlations are displayed in Table IV. The cross correlations are displayed for the entire series, for patients with carcinoma in situ, microinvasion, and invasion, and for patients with discrepant colposcopy–cone biopsy pathologic results. The squamocolumnar junction and endocervical curettage obviously do not perfectly cross correlate and one may suggest endocervical disease when the other does not. In the 14 patients with microinvasion or invasion who had both squamocolumnar junction and endocervical curettage evaluation, there were no patients with the squamocolumnar junction seen, but five of the 14 had a negative endocervical curettage result. Of note is that in the entire series, when the squamocolumnar junction was seen, the endocervical curettage result was positive in 7% and negative in 93%. When the squamocolumnar junction was not seen the endocervical curettage result was positive in 34% and negative in 66%. When the endocervical curettage result was positive the squamocolumnar junction was not seen in 62% and was seen in 38%. When the endocervical curettage result was negative the squamocolumnar junction was not seen in 20% and was seen in 80%. On comparison of all the cross correlations in Table IV, squamocolumnar junction visualization seems to be a more sensitive indicator of endocervical disease and of severe disease than the endocervical curettage result. Nevertheless the endocervical curettage occasionally reveals endocervical disease unsuspected by the squamocolumnar junction visualization and, when positive, is more often associated with severe disease than is nonvisualization of the squamocolumnar junction, as shown in Table V.

Exocervical lesion size as it relates to the severity of the ultimate pathologic diagnosis has also been analyzed. The size of the lesions was estimated by reviewing the diagrams of the lesions in the colposcopy logbook and then comparing lesion sizes for patients in the whole series with those of the patients with carcinoma in situ, microinvasion, and invasion. A small lesion was defined as no exocervical lesion or a lesion <8 mm^2. A large lesion was defined as an exocervical lesion >200

Table V. Association of microinvasion and invasion with squamocolumnar junction visualization, endocervical curettage result, lesion size, and age

	Entire series	*Microinvasion*	*Invasion*	*Chance of microinvasion or invasion (%)*
Squamocolumnar junction				
Seen	1623	6	0	0.37
Not seen	546	14	16	5.5
Endocervical curettage result				
Positive	154	3	10	8.4
Negative	888	2	3	0.56
Size of exocervical lesion				
Small (0-8 mm^2)	261	0	1	0.38
Medium (8-200 mm^2)	1524	15	13	1.8
Large (>200 mm^2)	259	8	5	5.0
Age (yr)				
15-18	190	1	0	0.53
19-20	348	0	0	0
21-25	717	5	2	0.98
26-30	350	5	0	1.4
31-40	241	3	4	2.9

>50	87	6	10	18
Entire series	2194	23	19	1.9

mm^2. Medium lesions were >8 and <200 mm^2. By this definition 13% of the entire group of 2044 patients without previous therapy had small lesions, 13% had large lesions, and 74% had medium lesions. Of 237 patients with carcinoma in situ 4% had small lesions, 19% had large lesions, and 78% had medium lesions. Of 42 patients with microinvasion or invasion 2% had small lesions, 31% had large lesions, and 67% had medium lesions. This demonstrates the increasing lesion size associated with more severe disease. Table V displays the correlation of lesion size with microinvasion-invasion. Particularly notable is the rarity of small lesions in microinvasive-invasive disease.

Increasing patient age is another important factor correlated with severity of pathologic results, nonvisualization of the squamocolumnar junction, and positive endocervical curettage results. The percentages of patients with carcinoma in situ, microinvasion, or invasion for each age group are: 15 to 20 years old, 3%; 21 to 25 years old, 8%; 26 to 30 years old, 13%; 31 to 40 years old, 23%; 41 to 50 years old, 25%; and over 50 years old, 39%. Age correlations with microinvasion-invasion are shown in Table V. The percentages of patients with positive endocervical curettage results for each age group are: 15 to 20 years old, 5%; 21 to 25 years old, 11%; 26 to 30 years old, 14%; 31 to 40 years old, 22%; 41 to 50 years old, 36%; and over 50 years old, 46%. The percentages of patients with nonvisualization of the squamocolumnar junction for each age group are: 15 to 20 years old, 7%; 21 to 25 years old, 15%; 26 to 30 years old, 20%; 31 to 40 years old, 37%; 41 to 50 years old, 81%; and over 50 years old, 90%.

Comment

Our analysis reveals that the colposcopy clinic was particularly successful in accurately identifying the 42 patients with microinvasive-invasive disease with absence of patients who were treated by cryotherapy and later found to have these more severe lesions. The important considerations in this outcome included eval-

uating the degree of Papanicolaou smear abnormality, the colposcopic biopsy pathologic results, the squamocolumnar junction visualization, and the use of cone biopsy and/or hysterectomy for the management of patients with severe dysplasia and carcinoma in situ. The endocervical curettage findings were less helpful. In the retrospective review it does not appear that the findings on endocervical curettage contributed significantly to the discovery of any of the 42 patients with microinvasion or invasion as none of the 18 of these patients who had an endocervical curettage had a positive result when the squamocolumnar junction was visualized. In this series severe dysplasia and carcinoma in situ were usually treated surgically regardless of endocervical evaluation. Cone biopsy in patients with severe dysplasia or carcinoma in situ on Papanicolaou smear or on colposcopic biopsy, even though the squamocolumnar junction was seen, led to the diagnosis of microinvasion in two of 23 patients with microinvasion. These patients were both seen before 1977, when endocervical curettage was not being done, and results of endocervical curettage may possibly have been positive in these two patients. However, our data would suggest that this probably would not have been the case. As displayed in Table IV, four patients later in the series who had microinvasion and who had both endocervical curettage and squamocolumnar junction evaluation included two with positive endocervical curettage results and two with negative results and the squamocolumnar junction was not seen in any of the four. All observers of the colposcopic approach have commented on the necessity of visualization of the entire lesion and the squamocolumnar junction if one is to rely on colposcopic biopsy to be most accurate in ruling out microinvasion and invasion.[1-10] Many have observed that even with squamocolumnar junction visualization the colposcopic biopsy does not totally exclude the presence of microinvasion and invasion (particularly the former) and our series confirms this observation.[1, 3-5, 7, 9]

Endocervical curettage has been considered by a number of observers and the usage varies from nonuse,[1, 2, 6] to use only when the squamocolumnar junction is not seen,[3, 4] to use only when it would contritube to the management,[10, 11] to use in all patients,[5, 12, 15] and some believe the results are always positive in patients with invasion.[12-14] Articles reviewing cases in which patients developed invasive disease after colposcopy and cryotherapy[15, 16] have led to the observation that endocervical curettage was often omitted in those with later invasion but these articles also reveal that endocervical curettage was done and the result was negative in a substantial number of the patients with later invasive disease. Many colposcopy series include a fairly small number of patients with microinvasion or invasion, but still attempts are made to arrive at conclusions regarding the role of squamocolumnar junction visualization and endocervical curettage in detecting these patients. Our series is larger than most but nevertheless we are reluctant to make conclusive statements about squamocolumnar junction visualization and endocervical curettage except to observe that neither is totally accurate in excluding microinvasion-invasion. Even when used in combination and in conjunction with the colposcopic biopsy they should not be expected to always exclude microinvasive-invasive disease. On the basis of our patients with microinvasion and the available literature it would appear that if one is to treat severe dysplasia–carcinoma in situ with cryotherapy then both squamocolumnar junction visualization and a negative endocervical curettage result should be present to exclude microinvasion-invasion to the maximal degree. On the basis of our data and those of others,[1-3] if one uses a surgical approach with more severe disease (severe dysplasia–carcinoma in situ) regardless of endocervical evaluation, then adding endocervical curettage evaluation to squamocolumnar junction evaluation for all patients does not appear to be of significant value. Others, however, suggest that endocervical curettage should be done even in those with only mild to moderate dysplasia on Papanicolaou smear and colposcopic biopsy and where the squamocolumnar junction is seen because it appears that even these patients will on rare occasion have a positive endocervical curettage result leading to the diagnosis of invasive disease.[7, 15]

Evaluation of the severity of the Papanicolaou smear and colposcopic biopsy results seem to be important correlates of the likelihood of associated microinvasion-invasion in our series. Some have implied that the severity of the disease on Papanicolaou smear or colposcopic biopsy short of microinvasion-invasion is not important in the selection of therapy as long as endocervical disease is ruled out by endocervical curettage and squamocolumnar junction visualization.[5, 17] Our data would not support this approach because of the strong correlation between Papanicolaou smear and colposcopic biopsy severity and ultimate diagnosis of microinvasion-invasion, plus the observation that squamocolumnar junction visualization and endocervical curettage will not always rule out microinvasion or invasion.

Exocervical lesion size has been correlated with the severity of the subsequent pathologic result by others,[18, 19] and it has been suggested that large lesion size may result in less accurate biopsies unless one samples the entire large lesion.[17-19] Our data are notable in revealing the particularly infrequent occurrence of small exocervical lesions in patients with microinvasion-invasion.

Age has long been correlated with an increasing incidence of many malignancies, and there is also an age correlation with severity of disease in the dysplasia–

carcinoma in situ–invasion continuum of cervical disease. This is demonstrated in our data as well as those of other observers.[2, 14] Increasing age is also correlated with squamocolumnar junction nonvisualization and positive endocervical curettage findings as documented by our data and those of others.[2, 14, 20] This appears related to the gradual migration of the squamocolumnar junction upward into the cervical canal because of the squamous metaplasia that occurs in all women. Notable is that these age correlations are infrequently incorporated into the management plans that have been proposed. It would seem reasonable that age should be integrated into the management plan as an important variable because of the increased likelihood of microinvasion-invasion in older patients as well as the existence of less concern in the older patient that conization or hysterectomy will interfere with childbearing.

The integration of these variables of Papanicolaou smear, colposcopic biopsy, squamocolumnar junction visualization, endocervical curettage, lesion size, and age into a management approach is somewhat complex because all are correlated with each other and all are predictive of the likelihood of finding microinvasion and invasion but none is perfect in that regard. Various possibilities in data integration will be the subject of a future report.

In summary a colposcopy clinic experience in evaluating 2194 patients with abnormal Papanicolaou smears is presented with a demonstration of the importance of various factors and of their multiple cross correlations.

Editors' note: This manuscript was revised after these discussions were presented. The scoring system referred to in the discussion and the treatment and follow-up data were deleted from the revised manuscript.

Discussion

Dr. Maurice J. Mueller, Crescent Springs, Kentucky. The sheer numbers of patients involved in this study testify to its importance. Certainly the presence of 42 patients with microinvasion or invasive disease constitutes a wealth of experience. This article is especially helpful for the generalist not working in a clinic-type situation, who may not do this many colposcopies in an entire lifetime. It has been said that most invasive cancers occurring after conservative therapy are in those patients treated by less experienced colposcopists.[1] The use of the author's scoring system appears to be an excellent scheme for the nonexpert colposcopist.

The data here again prove that even milder Papanicolaou smear abnormalities may be associated with advanced disease. There were five patients with mild or moderate dysplasia on Papanicolaou smear who were shown to have microinvasion or invasion. This demonstrates the importance of evaluating all cases of dysplasia with colposcopy. Unfortunately, there are still some localities and some laboratories that choose to follow up these cases of milder dysplasia with repeat Papanicolaou smears only. Even though this association is not common, any delay in the diagnosis of advanced disease could obviously be disastrous.

Although not part of his scoring system, it would be interesting to know if the author considered the presence of an abnormal vascular pattern and its relation-

ship to advanced cervical disease. Sillman et al.,[2] in 1981, reported the occurrence of atypical vessels with invasive cervical cancer. Of their 60 patients with atypical vessels on colposcopy, all had either carcinoma in situ or invasive cancer. They felt this relationship to be great enough to recommend conization if the cervical biopsy did not show invasion.

This article includes endocervical curettage in the evaluation. Although the actual technique of endocervical curettage can vary greatly among individuals, I feel that it is important in order to get the maximum amount of information. In the landmark article of Townsend et al.,[3] in 1981, it was recommended that every patient with an abnormal smear undergo an endocervical curettage unless pregnant. Their review included 17 patients who did not have an endocervical curettage at the time of colposcopy, who then developed invasive cancer after cryotherapy. In a study by Hatch et al.,[4] in 1985, the endocervical curettage contained neoplastic epithelium in all 15 of the patients with invasive cancer, and in seven patients it was the only diagnostic parameter that indicated invasion.

It is significant that no patient in this present study had cryotherapy and was later found to have microinvasion or invasion. This indicates a well-thought-out triage procedure and a high degree of colposcopic skill and diligence. This is also borne out by five particular cases of microinvasion diagnosed by colposcopic biopsy. After conization or hysterectomy, these patients were found to have no residual microinvasion or invasion. Apparently the entire lesion had been removed by the biopsy in these cases.

The author admits that follow-up in the cryotherapy group was less than perfect. The follow-up problem is unfortunately quite common in large clinic populations. Of the 565 patients treated with cryotherapy, only 372 (66%) had a follow-up of at least one Papanicolaou smear. Of these 372, 101 patients had at least one follow-up Papanicolaou smear showing dysplasia. Thus there were 101 known cases of possible persistence of disease. Forty-seven of these 101 had subsequent biopsies, with 25 having dysplasia. The long-term follow-up of the 101 patients was not mentioned.

This very large series allowed the development of a quite practical regimen for the colposcopic evaluation of the abnormal Papanicolaou smear. With the multiple variables involved in technique, the Wetrich scoring system gives a more objective viewpoint. Application of this system should bring optimum results in the management of these patients.

DR. KENNETH L. NOLLER, Rochester, Minnesota. I would like to congratulate Dr. Wetrich on his exhaustive efforts to document the experience of the University of Iowa Colposcopy Clinic for a period of 13 years. I would also like to thank him, as a clinician interested in colposcopy, for once again demonstrating to us that colposcopy is a safe and effective method for the evaluation and treatment of patients with cervical intraepithelial nneoplasia. It is indeed unfortunate that the short time interval allowed for presentation of papers at this meeting does not permit him to more fully develop the wealth of material that is found in the full manuscript that he has submitted. However, the area he has chosen to review with us today is certainly the most interesting and most controversial portion.

During the period of this study, 41 patients in whom the cervix was present were diagnosed as having either microinvasive or invasive squamous cell neoplasia of the cervix. All of these were identified as a part of the initial evaluation and none was found for the first time after outpatient therapy. I believe that there can be little doubt that colposcopy is the indicated procedure of choice following the report of an abnormal Papanicolaou smear.

In an attempt to increase the predictive value of the colposcopic images seen, Dr. Wetrich analyzed the factors that are commonly associated with invasive cancer. Similar to other investigators, he found that the severity of the Papanicolaou smear, the diagnosis obtained by colposcopic biopsy, the report of the endocervical curettage, the lesion size, and the age of the patient were all positive predictors of invasive disease. However, Dr. Wetrich then goes on to suggest that the "branching algorithm" approach, which is the basis for the colposcopic method, is outdated. He states: "This approach does not allow for proper integration of the available factors . . ." Based on this opinion, a scoring system was developed to aid in prediting which patient would have invasive cancer.

I believe that this is an improper conclusion based on the results of the study. Dr. Wetrich's study has shown that the method used during the study period, the "branching algorithm" approach does work. Table I shows how the usual approach to colposcopy was applied in the 16 evaluable cases of frank invasion that were discovered during this study. No invasive cancer was missed with this approach.

Table II shows the colposcopic technique applied to the 21 evaluable cases of microinvasion discovered during the series. It is not clear how one of the patients was identified. This case was in a 23-year-old patient with a Papanicolaou smear showing grade 3 cervical intraepithelial neoplasia, carcinoma in situ on the biopsy, a satisfactory examination, and a moderate lesion size. No endocervical curettage was performed. There-

↓		
Satisfactory examination, 0	→ Colposcopic biopsy: invasion,	14
	microinvasion,	2
	cervical intraepithelial neoplasia,	3

Table II. University of Iowa colposcopy series: Microinvasion

Cases, 23 → incomplete records, 2
↓
Colposcopy, 21 → unsatisfactory examination, 14 → conization
↓
Satisfactory examination, 7 → microinvasion on biopsy or examination, 11 → conization
↓
Satisfactory biopsy, 2 → disparity between Papanicolaou smear and biopsy, 1 → conization
↓
Endocervical curettage, 1 → not done

fore this is an unevaluable case since it is quite likely that an endocervical curettage would have picked up the small microinvasive cancer that was found in the conization specimen.

The proposal for a scoring system is, in my opinion, unwarranted. This large study has failed to show a single case of invasive cancer in which the diagnosis was missed. This laudable record was achieved with the old system. Why then change to a new system?

The graphs shown by Dr. Wetrich demonstrate a bimodal distribution of point values for the cases seen with carcinoma in situ and severe dysplasia. This suggests that the system adds nothing to the usual colposcopic technique. In fact the distribution, as demonstrated by the graphs, argues against the use of the system. The first peak on the graph is a result of the high value assigned to lesions of grade 3 cervical intraepithelial neoplasia or worse and the second peak is due to nonvisualization of the squamocolumnar junction or a positive endocervical curettage result. There appears to be little interaction of these variables.

Additionally, with the scoring system known, it is possible to "invent" patients who should probably have conization but do not receive enough points to require conization. For example, a 21-year-old woman with mild to moderate dysplasia and a small lesion with a nonvisualized transformation zone would have a total of only 16 points by the proposed scoring system. This would make her a candidate for cryocautery even though the examination was unsatisfactory. Likewise, an 18-year-old woman with mild to moderate dysplasia and a positive endocervical curettage result with a small lesion would also be a candidate for outpatient therapy. Neither of these patients fulfills the accepted criteria for outpatient therapy. Although these patients are totally fictitious, they are not unrealistic, and it is certainly possible that such women would eventually present at the clinic and be mismanaged if the scoring system were strictly applied. However, the "branching algorithm" approach would correctly require conization in both cases.

I would like to ask Dr. Wetrich two questions: First, is the scoring system used at the University of Iowa Colposcopy Clinic at the present time? Second, if the system is presently being used, would the two fictitious cases that I have just proposed be treated by outpatient cryocautery in the face of an unsatisfactory examination or a positive endocervical curettage result?

In conclusion, I would like once again to congratulate Dr. Wetrich on an excellent piece of work documenting the usefulness of colposcopy. While he and I differ slightly on the conclusions that should be drawn from the study, this article is a most important addition to our current approach toward the correct diagnosis and management of patients with cervical intraepithelial neoplasia.

Dr. D. Foley, Milwaukee, Wisconsin. In the five patients with a Papanicolaou smear showing mild dysplasia, did the repeat Papanicolaou smear still show mild dysplasia?

Dr. Wetrich (Closing). Dr. Mueller asked about the colposcopic appearance of the lesion as a possible variable that we might incorporate into our management. As anyone who has done colposcopy knows, we think

we can somewhat predict the severity of the lesion by its appearance. We have not really made any attempt to integrate that into our plan of management because it seems to us that ultimately we depend on the biopsy, regardless of what the lesion looks like, so it would not be too helpful to add that into our management plan. Certainly one does get impressions, but I guess if a lesion looked like invasive cancer and the biopsy results did not show that, I would not change my management just based on the appearance.

Dr. Mueller also commented on the fact that our follow-up on patients who underwent cryotherapy was not ideal, and I would agree with him. I commented on that in the full manuscript. About one third of our cryotherapy patients were not followed up at our institution. In our institutional setting many patients come from some distance away, and in many cases it is much more convenient for them to have follow-up through their local physician or local clinic. We do not insist that they return to University Hospitals for routine follow-up after cryotherapy.

It certainly is possible that some of those patients did have microinvasion or invasion that we did not know about. We do know that many of them are referred back to us if they have recurrent abnormalities after cryotherapy, and we would like to think that if they had microinvasion-invasion they would also be referred back to us; but certainly that is an appropriate criticism.

Dr. Noller presented an analysis of our case list of patients with microinvasion-invasion and what might have happened in those patients if one used a fairly simple branching algorithm approach depending primarily on the presence or absence of endocervical disease. It is true that all of our cases of invasion would have been detected with this approach. On the other hand, in two of our patients, microinvasion might have been missed with this approach. In both patients the squamocolumnar junction was visualized and a colposcopic biopsy specimen did not show microinvasion. These patients were from the early part of our series when we were not doing endocervical curettage. It is possible that the endocervical curettage findings might have been positive in these patients had the procedure been done. However, only 7% of our patients who had visualization of the squamocolumnar junction had a positive endocervical curettage result, so these patients probably would not have had a positive finding at curettage. There may be a certain amount of conjecture in that, but it seems like a reasonable conclusion.

In addition to our data, it should be noted that there are numerous other series in the literature at the present time that document cases of microinvasion not diagnosed on colposcopic biopsy even though the colposcopy was satisfactory, with the squamocolumnar junction seen. Also data in the literature demonstrate a number of patients with microinvasion or invasion who had negative endocervical curettage results, as was found in our series. So, on the basis of our data and other published data, it seems that total reliance on endocervical disease evaluation as the only indication for cone biopsy may be inappropriate. We would like to think that adding in the additional factors might lead to a more reasonable approach.

Dr. Noller commented that perhaps a more formalized statistical multivariant analysis would be appropriate. I think that is an excellent idea, and I intend to pursue it.

Dr. Noller also gave a couple of hypothetical examples of patients who were borderline cases and questioned whether that was really the appropriate way to manage the patients. Both of these patients had mild to moderate dysplasia and were also in the very young age group and had small lesions. My only comment on that would be that in our series of patients, in all those who had less than moderate dysplasia (including mild or mild to moderate dysplasia) as the worst abnormality on Papanicolaou smear, colposcopic biopsy, or endocervical curettage, there were no cases of microinvasive or invasive cancer; a series of about 700 patients would fit this description. Dr. Noller is picking a borderline situation that people might differ with, but I think the recommendation of the scoring system would not be far off base.

Dr. Noller also asked about the use of the scoring system in our clinic. Perhaps I should comment a bit more about the clinic. Specifically, I myself, in conjunction with the residents in training, did all the initial colposcopic evaluations of these patients. After colposcopic evaluation, their management was then the responsibility of other staff physicians, and during the course of the study about 10 different staff gynecologists were involved in making the postcolposcopy decisions. Obviously this is not going to lead to an entirely consistent approach, because everyone has different ideas about management, so we did not have any strict protocol on postcolposcopy management.

Almost all of the patients with carcinoma in situ did have cone biopsy regardless of endocervical involvement. A great majority of patients with severe dysplasia also had cone biopsy regardless of the endocervical evaluation. In addition, in patients with a milder disease a variety of things were done. Women who had mild dysplasia without endicervical disease were of course almost all treated with cryotherapy, but if they had endocervical disease a number of things were done. Some were just followed up with Papanicolaou smears, some had cryotherapy, and some had cone biopsy, so there was not really a very consistent approach to these patients with mild disease.

We have not had any strict protocol in terms of how these cases have been managed. Right now we are going through a transition in the way the clinic operates. We hope to have a more systematic approach and to be able to incorporate the principles of the scoring system.

Dr. Foley had a question about the patients with mild disease on Papanicolaou smear. I think he was referring to patients who had mild dysplasia and who were found to have microinvasive or invasive disease. In the data given here, only the Papanicolaou smear taken at the colposcopy clinic is included. Obviously these patients

had Papanicolaou smears taken before being referred to the colposcopy clinic, and some had Papanicolaou smears after that. I do not have a detailed breakdown of data to answer his question, but in some cases, yes, the additional Papanicolaou smears showed more than mild dysplasia. I cannot give you a more detailed breakdown on that specific question, but in some cases the patients had worse than mild dysplasia on subsequent or prior Papanicolaou smears.

Chorionic villus sampling in continuing pregnancies

I. Low fetal loss rates in initial 109 cases

Sherman Elias, M.D., Joe Leigh Simpson, M.D., Alice O. Martin, Ph.D., Rudy Sabbagha, M.D., Allan Bombard, M.D., Barbara J. Rosinsky, B.S., and Lora D. Baum, M.S.

Chicago, Illinois

Among the first 150 women who agreed to have chorionic villus sampling after receiving counseling and giving informed consent, 41 proved ineligible. In six (5.5%) of the remaining 109 cases in which chorionic villus sampling was performed, we were unsuccessful in obtaining an adequate amount of villi to permit diagnostic testing. In the single loss, fetal viability was confirmed 2 weeks after sampling; however, fetal death became evident 3 weeks later. In four (3.7%) cases the pregnancies were terminated because of abnormal results, and in one (0.9%) case the pregnancy was electively terminated after normal results. Among the 41 completed pregnancies no anomalies were evident in the infants. There were two premature deliveries; one of these two infants died shortly after birth following premature rupture of the membranes at 29 weeks' gestation. All undelivered cases were progressing normally at the time of submission. (AM J OBSTET GYNECOL 1986;154:1349-52.)

Key words: Chorionic villus sampling safety

At the 1984 annual meeting of The Central Association of Obstetricians and Gynecologists we presented our initial experience in developing a chorionic villus sampling program at Northwestern University.[1] At that time we stated the following: "Chorionic villus sampling for first-trimester prenatal diagnosis has the potential of becoming an attractive alternative to genetic amniocentesis. Prior to becoming a standard, however, considerable caution and monitoring is necessary to establish the accuracy and safety of the procedure." In this pursuit, we wish to present our continued experience in the technical aspects and safety of chorionic villus sampling. In our companion paper,[2] we present our results with respect to cytogenetic reliability and accuracy.

Material and methods

In August 1983 we initiated our chorionic villus sampling program at Northwestern University by developing surgical and laboratory experience in a series of 58 volunteers undergoing elective first-trimester abortion (6 to 12 weeks' gestation).[1] Our initial experience was sufficiently encouraging that in March 1984 we sought and obtained approval from the Institutional Review Board of Northwestern University to offer chorionic villus sampling in continuing pregnancies. The following were considered indications for the procedure: (1) advanced maternal age (usually age ≥35 years; (2) previous trisomic offspring; (3) parent with a balanced structural chromosomal rearrangement; and (4) fetus at high risk for a detectable mendelian disorder (for example, Tay-Sachs disease, sickle cell disease).

A preliminary ultrasound examination was performed on all patients fulfilling these criteria who were

interested in chorionic villus sampling. Only patients whose pregnancies were between 7 and 11 weeks' gestation, based on onset of the last menses and confirmed by ultrasonographic measurement of the fetal crown-rump length (9 to 41 mm) remained eligible. Patients were excluded if (1) fetal viability was not confirmed by ultrasonographic visualization of fetal heart motion; (2) multiple gestation was detected; (3) pathologic conditions coexisted that conferred increased risk in performing chorionic villus sampling (for example, active genital herpes simplex infection, cervical pathologic findings, severe cervicitis, undiagnosed cervical lesion, active uterine bleeding); (4) large submucous uterine leiomyomas precluded reasonable access to the chorionic villi; (5) a markedly angulated cervical canal precluded ready catheter passage; and (6) the placenta was fundal and deemed inaccessible. (With increasing operator experience this last exclusion criterion became less applicable.) All eligible patients underwent formal genetic counseling and gave informed consent for chorionic villus sampling.

We basically continue to perform the procedure, as previously described,[1] in an ambulatory surgical suite to minimize the risk of infection. We use a 2.1 mm outer-diameter radiopaque Teflon catheter (E-Z Cath, Deseret Pharmaceutical Co., Inc., Sandy, Utah), trimmed by scissors to fit snugly over a blunt-ended aluminum stylet. Use of the catheter for this purpose is under an investigational device exemption approval from the Food and Drug Administration. If additional attempts are required to obtain an adequate specimen, a fresh catheter is used each time.

A real-time mechanical sector transducer (3.5 MHz) is employed to visualize the uterus and to guide the catheter into the optimal site of the placental substance. After aspiration, villi are transferred to a Petri dish containing 5 ml of modified Ham's F-12 media and inspected through a dissecting microscope (10×). The quantity of tissue is judged to be adequate if at least 5 mg of villi were obtained. Optimal samples weigh 15 to 20 mg. The quantity of tissue is estimated by comparison to a predetermined reference standard in which varying amounts of villi were weighed and photographed. Specimens are immediately transported to our laboratory for processing. The cytogenetic methods we are currently using are provided in our companion paper.

Following this procedure, fetal heart movements are verified by ultrasonographic visualization, and the patient is monitored for at least 30 minutes for any untoward effects. (None has been observed.) Patients at risk for Rhesus isoimmunization receive 300 μg of anti-D immune globulin if their indirect Coombs' test is negative.

Patients are also routinely contacted by telephone 3 days following the procedure. At 15 weeks' gestation an ultrasound examination is performed to detect overt fetal malformations and to assess fetal growth. Maternal serum α-fetoprotein is also determined.

Because maternal cell contamination in the chorionic villus sampling specimen could lead to an erroneous fetal diagnosis, our investigative protocol provides the option for patients with a 46,XX complement to have a subsequent confirmatory genetic amniocentesis at no additional cost.

Results

Among 188 women screened for chorionic villus sampling, 41 were considered ineligible, and 38 declined the procedure (Table I). The indications for prenatal diagnosis in those 109 women who underwent the procedure are summarized in Table II. Sampling was usually carried out at the ninth or tenth week (Table III). In six of the 109 (5.5%) cases we were unsuccessful at obtaining an adequate amount of villi to permit diagnostic testing. All six subsequently underwent successful amniocentesis. Table IV correlates the number of transcervical catheter passes correlated with the success or failure of obtaining a specimen adequate for analysis. The overall success rate was 94.5%.

Of the 103 successful samplings, 97 were cytogenetically normal: 46,XX (50); 46,XY (47). In six cases a

chromosomal abnormality was detected from the chorionic villus sampling specimen, as will be discussed in our companion paper. In one of our early cases (No. 8) the chorionic villus specimen showed a 45,XX complement, but the infant was male. Analysis was based on three cultures; no metaphases from the direct method were available. This finding suggested maternal cell contamination. The pregnancy at risk for Niemann-Pick disease was determined to be unaffected (biochemical assay performed by Dr. David Wenger, Denver, Colorado). This pregnancy was still undelivered at the time of submission.

Pregnancy outcomes of all 109 women undergoing chorionic villus sampling are summarized in Table V. Only one fetal loss has occurred, that being detected 5 weeks following the procedure. An ultrasound scan was normal 2 weeks after chorionic villus sampling, indicating that fetal death occurred 2 to 5 weeks after the sampling. In this case, two catheter passes were required to obtain an adequate sample that subsequently proved to be 46,XX. The patient experienced intermittent vaginal spotting during the first week after the procedure, but fetal heart tones were confirmed by Doppler ultrasound 2 weeks later. However, fetal heart tones were absent 5 weeks after chorionic villus sampling; fetal death was confirmed by ultrasonographic examination.

In two cases several milliliters of clear yellow fluid was inadvertently aspirated from the catheter during the initial passage, and the procedures were discontinued. However, in neither case did the gestational sac collapse, and in each fetal heart motion was normal. Both patients were followed with serial ultrasonographic examinations, with no evidence of oligohydramnios, leakage of fluid, or infection. The first patient underwent subsequent amniocentesis at 16 weeks, which showed normal 46,XY complement. This patient has been delivered of a healthy 4665 gm infant. The second patient also underwent amniocentesis with results pending at the time of submission; this pregnancy is progressing normally.

Table V. Pregnancy outcomes of the 109 women undergoing chorionic villus sampling

	n	%
Number of patients sampled	109	
Unsuccessful samplings	6	5.5
Fetal losses	1	.9
Terminated because of abnormal results	4	3.7
Elective abortion after normal results	1	.9
Delivered at term	41	
Delivered prematurely*	2	
Continuing pregnancies	54	

*In one case delivery was at 34 weeks with normal outcome; in the second case neonatal death occurred at 29 weeks.

Comment

Although still investigational, chorionic villus sampling is already welcomed as an important advance in prenatal diagnosis. However, despite worldwide experience with more than 7000 procedures,[3] precise data with respect to safety are not yet available. We have

previously addressed the complexities of attempting to assess the safety of chorionic villus sampling.[1-4] Suffice it to repeat that the rate of 4% to 5% fetal losses observed worldwide after chorionic villus sampling is an absolute rate that must be corrected for a host of confounding variables: (1) accuracies in the identification and timing of spontaneous fetal loss rates, (2) maternal history of prior induced abortions, (3) parental cytogenetic factors (recurrent aneuploidy, translocations, inversions), (4) maternal age, (5) gravidity, (6) smoking, (7) alcohol consumption, and (8) environmental factors (for example, exposure to infectious agents, drugs, or chemical toxins).

In this context our own initial experience is still most encouraging. The overall success rate of obtaining a specimen adequate for analysis was 94.5%, but in 56.9% of samplings an adequate specimen was obtained with a single catheter pass. In an additional 23.9% of cases, two catheter passes were required; 13.8% of cases required three or more passes; in 5.5% we were unsuccessful. Only one fetal loss occurred among our first 109 cases, and this took place at least 2 weeks after the procedure. The fetus was determined to be chromosomally normal, and no cause could be documented for the loss.

Of special interest are the two cases in which fluid was inadvertently aspirated during chorionic villus sampling. In each, expectant obstetric management was successfully followed. Although the exact origin of the aspirated fluid could not be determined, failure of the gestational sac to collapse suggests to us that the fluid could have been derived from the space between the amnion and chorion. Alternatively, early amniocentesis may not necessarily be deleterious. In neither case was there evidence of oligohydramnios, transcervical fluid leakage, or infection. If there is documentation of an intact gestational sac by ultrasound, we now believe that expectant management is a reasonable option provided (1) couples are informed of potential maternal and fetal risk (for example, oligohydramnios, infection, spontaneous abortion); and (2) close fetal and maternal surveillance is possible to monitor indices of developing infection, fetal growth, and amniotic fluid volume. On the other hand, we would predict the risk of intrauterine or deformation infection to be great if the gestational sac is observed to collapse at the time of chorionic villus sampling. If such a pregnancy were allowed to continue, the risk of continued amniotic fluid leakage and oligohydramnios leading to fetal deformations would be substantial.[5] Accordingly, we would recommend that pregnancy termination be seriously considered in such cases.

Our overall low complication rate following chorionic villus sampling could be attributed to various factors. First, it could merely reflect the vicissitudes of yet relatively small numbers. However, we believe that our low total fetal loss rate (0.9%) in the first 109 cases may be compared favorably with the 2.0% to 4.4% absolute loss rates reported to the International Fetal Diagnosis Registry by the four most experienced centers worldwide.[3] Of course, we again emphasize that neither their data nor ours take into account the background fetal loss rates, nor are they corrected for the numerous confounding variables alluded to earlier. Best estimates at this time suggest that *procedurally related* losses will be in the range of 1% to 2%. Second, our sample (that is, primarily upper socioeconomic, white) could have been selected from a group of women less likely to undergo complications than other groups. Differences in nutritional status, number of sexual partners, parity, and other factors could exist. Third, our experience in performing chorionic villus sampling in a large series of women immediately before elective abortions could have permitted the two obstetricians performing the procedure to become adept with its technical nuances. Fourth, our conservative approach in not even attempting chorionic villus sampling in certain cases (for example, multiple gestation, large uterine leiomyomas, cervicitis, spotting) may have reduced the potential for complications. Fifth, the risk for infection could have been minimized by performing chorionic villus sampling in an ambulatory surgical suite and in using a new catheter for each attempt at obtaining villi.

In conclusion, we remain optimistic that chorionic villus sampling will eventually become a standard diagnostic technique for first-trimester prenatal diagnosis. At present, however, it must still be regarded as investigational and not yet an accepted alternative to midtrimester amniocentesis. More definitive data comparing risks and accuracy of chorionic villus sampling as compared to amniocentesis will have to await data from collaborative studies under way in the United States, Canada, and Europe.

Chorionic villus sampling in continuing pregnancies

II. Cytogenetic reliability

Alice O. Martin, Ph.D., Joe Leigh Simpson, M.D., Barbara J. Rosinsky, B.S., and Sherman Elias, M.D.

Chicago, Illinois

Cytogenetic analysis was performed on 103 chorionic villus samples. Analysis of the 103 samples revealed six abnormalities. In three of the six the abnormalities were confirmed in fetal or neonatal tissue (47,XY, +13; 46,XY, t(13q13q); 45,X). In three samples the abnormalities detected were not confirmed; in two of the three the abnormalities were detected only in long-term cultures, whereas in the other samples the abnormality was restricted to direct analysis of the villi after overnight incubation. Our initial experience leads us to conclude that certain abnormalities in chorionic villus sampling may not be indicative of fetal abnormalities; 45,X/46,XX or 45,X/46,XY mosaicism is such a complement. Discrepancies between cytogenetic analysis of intact villi processed soon after sampling and of cells grown in culture can be managed by adhering to several suggested guidelines and by liberal use of confirmatory amniocentesis. (Am J Obstet Gynecol 1986; 154:1353-62.)

Key words: Chorionic villus sampling, cytogenetic reliability

Introduction of chorionic villus sampling as a routine diagnostic service not only requires confirmation of its safety but also its diagnostic accuracy. In our companion paper[1] we consider surgical techniques and safety of chorionic villus sampling. In this contribution we restrict our remarks to cytogenetic techniques and diagnostic accuracy in those 103 cases in which specimens were obtained. We propose guidelines for handling discrepancies between analysis of intact villi processed after overnight incubation and of cells derived from the villi and grown in tissue culture.

Material and methods

General approach. Since initiation of our chorionic villus sampling program, laboratory methods have evolved and expanded to improve quality of cytogenetic preparations, to increase efficiency, and to maximize diagnostic accuracy. Our initial methods have been described previously.[2] We continue to use two types of preparations: (1) direct analysis of mitoses present in intact chorionic villi, these cells presumed to have originated from budding cytotrophoblasts, and (2) analysis of cultured cells, the cultures having been initiated from mesenchyme cores of villi. We have performed cytogenetic analysis of cultured cells on all 103 subjects. "Direct" preparations were also successful in 79 cases. In some earlier patients analysis of intact villi was not always possible because (1) insufficient villi were obtained to attempt both types of preparations or (2) quality of the direct preparations was too poor to warrant analyses. However, only once among our last 59 specimens were both direct and culture methods not available.

Our current protocol is to visualize the specimen immediately after it has been obtained, with use of a dissecting microscope transported to the operating suite. We seek to determine whether at least 5 mg of villi have been obtained. If not, the obstetrician may elect to perform up to two additional aspiration(s). The specimen(s) is then transported to the laboratory in a 100 mm Petri dish containing 15 ml nutrient media, usually Ham's F-12 supplemented with heparin, penicillin, and streptomycin. The specimen is further examined under a microscope (10×) located in a horizontal flow hood (Edgeguard). If the specimen is extremely bloody, it is filtered through a 115 ml, 5 μ millipore filter unit (Nalgene Type A) before dissection. An estimate of the amount of material obtained is made by comparison with photographs of previously weighed villi (Fig. 1). Villi are then identified, dissected from nonvillus-appearing material, and washed in Hanks basic salt solution containing penicillin and streptomycin.

If the total specimen is <5 mg, we may elect to proceed with a culture only, bypassing the direct method.

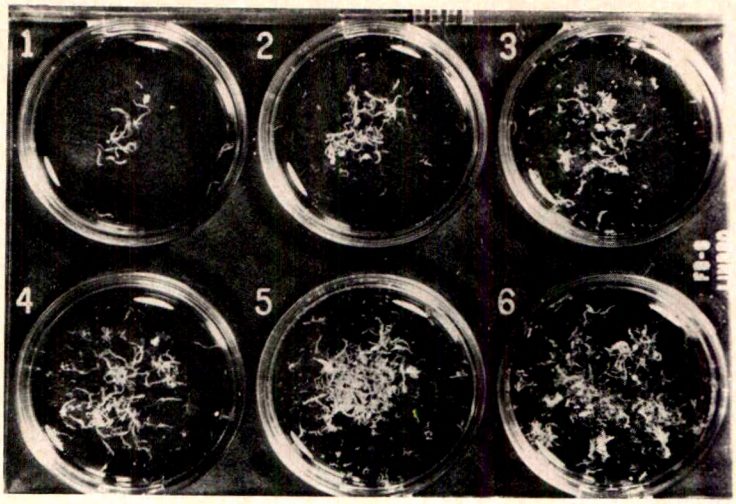

Fig. 1. Amount of dispersed chorionic villi in 5 to 40 mg aliquots.

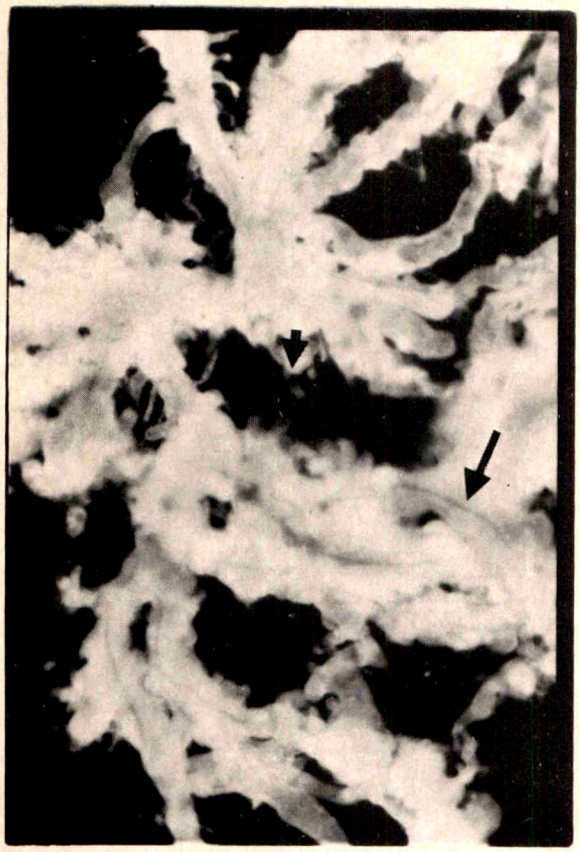

Fig. 2. Portion of chorionic villi showing buds *(short arrow)* and capillaries *(long arrow)*.

If both methods are to be attempted, villi are divided approximately equally for direct and culture preparations. The optimal-looking pieces (that is, villi with buds and capillaries) are allocated for the direct method.

Preparation of intact villi for analysis (direct method). Villi with buds and capillaries (Fig. 2) are necessary for the direct preparations. Such villi are placed in 2 ml of Chang's medium and incubated overnight at 37° C in an open system (5% carbon dioxide in balanced air). Specimens can also be processed immediately, but the mitotic index seems to increase when processed following overnight incubation (24 hours). Colcemid (final concentration, 0.15 μg/ml) is added for at least 3 hours. The medium is then aspirated, and 2 ml of 0.8% sodium citrate warmed to 37° C added. The specimen is left at room temperature for 20 minutes, following which the hypotonic solution is replaced with 2 ml of freshly prepared and chilled fixative (5 methanol/2 glacial acetic acid), and then chilled for 15 minutes at 4° C. This fixation is then repeated twice. The fixative is next aspirated, and the villi are allowed to air dry. They are then covered for 5 minutes with a few drops of 60% glacial acetic acid in distilled water. A small amount of the previously described 5 : 2 fixative is then added, the villi are vigorously aspirated up and down the pipette, and the suspension transferred to microscope slides.

Culture initiation. To initiate cultures, we first clean villi as already described. Photographs of villi are taken to document morphology of specimens used to initiate a given culture (A, B, C, etc.). This information will be used to determine (1) appearance of tissue in preparations in which maternal contamination is later demonstrated; (2) appearance of villi when a chromosomally abnormal complement is detected; (3) relationship between (a) villi appearance and quantity and (b) growth rate and quality of preparations. Two types of cultures are then prepared. In one type we use only prolonged trypsinization, whereas in the other we treat villi with trypsin ethylenediaminetetraacetate (EDTA) followed by collagenase. If only a few villi are available, the latter type is preferentiallly initiated because of the shorter time until analysis can proceed.

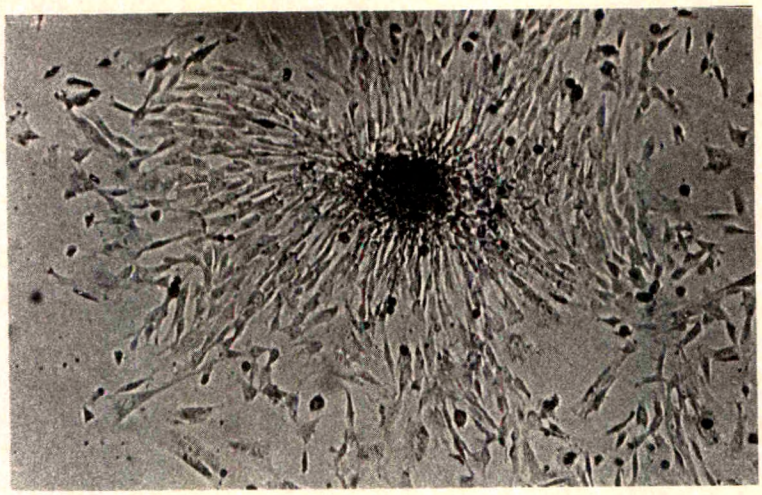

Fig. 3. A growth center in a culture derived from chorionic villi mesenchyme.

Table I. Indications and results

	No.	*46,XX*	*46,XY*	*Abnormalities*
Maternal age >35 years	91	48	43	45,X 47,XY,+13 46,XY/47,XY,+15* 45,XY,t(4;15)† 45,X/46,XX
Maternal age <35 years	4		4	
Previous trisomic offspring (two live-born, three amniocentesis, 1 chorionic villus sampling)	6	4	2	
Translocation heterozygosity—45,XX,t(13q13q)	1	1		46,XX,t(13q13q)
Niemann-Pick disease	1		1	

*Mosaicism was found in only direct cultures. Normal male fetus confirmed on amniocentesis.

†45,XY,t(4;15),(4qter→4p15 :: 5q→ 15qter. Because of amniotic sac puncture, only one small piece of villus was obtained. These results are from one culture.

Trypsinization culture method. After dissection and cleaning, villi are placed in a 60 mm Petri dish containing 3 ml of 0.25% trypsin. The dish is placed on a agitator for 2 hours. If villi are large and multibranched, the trypsinized villi are then filtered through a wire mesh. If pieces are small or individually identified, they are merely "swished" in the trypsin to remove debris adhering to the mesenchyme core. In either case a further 30-minute exposure to trypsin is employed, again with the Petri dish placed on the agitator. Pieces of villi are then washed in several changes of Chang's medium (open or closed system types) and placed into flaskettes (Lab Tek).

Trypsin-EDTA-collagenase culture method. After dissection and cleaning as previously described, villi are placed in 3 ml of trypsin-EDTA for 2 hours. Pieces of villi are then swished and washed to remove debris and placed in a 60 mm Petri dish with 5 ml of Chang's medium and 1 mg/ml of collagenase (Sigma Type V, 410 U/mg) overnight (13 to 17 hours). The suspension is then centrifuged (1000 rpm for 10 minutes), washed with supplemented medium (Chang's or minimal essential medium), and plated in flaskettes (Lab-Tek).

Subsequent culture and harvest. Irrespective of whether the trypsinization method or the combined enzyme method is used, cells usually attach in 1 to 2 days. Growth centers (Fig. 3) are classified as C (chorionic villus type cells, which are morphologically similar to "AF" cells observed in amniotic fluid cultures); E2 (epithelial-type cells, but cells which are *not* similar to epithelial cells characteristically observed in amniotic fluid cultures); F (fibroblast-like cells)[3]; or other. Incidentally, chorionic villus growth centers appear different from those observed in amniotic fluid cultures. The former show well-defined, central aggregates of cells surrounded by peripherally growing cells.

Cultures are monitored daily until the mitotic rate is sufficiently high to warrant harvest. The first cultures are ready for analysis at about 5 days and are those prepared by the trypsin-EDTA-collagenase method. Harvest is generally performed in situ on primary cultures, that is, enzymes are not used to disperse cells

Table II. Chorionic villus sampling abnormalities

	Direct preparation	*Culture*	*Confirmation*
47,XY,+13	UA	+	Yes (abortus)
45,X/46,XX	UA	+*	No (abortus)
46,XY,t(13q;13q)	+	+	Yes (abortus)
45,X	+	+	Yes (abortus)
45,XY,t(14p;15q) (unbalanced)	UA	+	No (amniocentesis)
46,XY/47,XY,+15	+	−	No (amniocentesis)

UA = Unavailable or unanalyzable.

*Fifteen 45,X cells were obtained from two cultures said to be initiated with villi. Sixteen 46,XX cells were obtained from two cultures with less optimal specimens at initiation. Consequently it was assumed likely that the sixteen 46,XX cells were maternal in origin.

from their primary growth centers. However, cultures may be subcultured or treated with enzymes to disperse cells within the flaskette (1) if only a single culture is available, (2) if large numbers of metaphases are required for analysis, or (3) if especially high-quality karyotypes are needed.

Culture harvest then proceeds. We use 0.7% of sodium citrate for 20 minutes as a hypotonic solution, followed by four changes of methanol/glacial acetic acid (5:2) fixative. Microscopic slides are prepared from the suspension-containing cells and are aged at least overnight before being treated with pancreatin and stained with Wright's Giemsa stain.

Cytogenetic analysis. Ideally, 20 cells are analyzed from direct preparations and 20 from cultures. We especially prefer this number if a normal female chromosomal complement is encountered. If the complement is male, only 10 cells from each are counted. If mosaicism is detected, 50 to 100 cells are analyzed.

Results

Cytogenetic analyses have been completed for 103 patients with continuing pregnancies (Table I). Ninety-seven were diagnosed normal: 47 male (46,XY) and 50 female (46,XX). However, there was one instance

Table IIIB. Incidence of aneuploidy in chorionic villus sampling according to gestational age (all maternal ages)*

of maternal cell contamination leading to a misdiagnosis of sex. There were six abnormal complements (Table II).

Of the 97 normal complements, eight were confirmed by cytogenetic analysis of amniotic fluid cultures. (Amniocentesis is offered to all women whose chorionic villus sampling complement is 46,XX). An additional 35 diagnoses were confirmed at birth with respect to sex and/or normal phenotypes. One normal pregnancy was electively terminated, and 54 pregnancies are still in progress.

The status of the six abnormal complements (Table II) is as follows: (1) The 47,XY,+13 case was confirmed on an abortus specimen, and thus was considered as validated. (2) The 45,X/46,XX mosaic was *not* confirmed on abortus material that was definitely fetal in origin; all 100 abortus cells were 46,XX. (3) The 45,XY,t(4;15)(4qter→4p15::15q15→15qter) unbalanced complement was confirmed at neither amniocentesis nor delivery (46,XY). A phenotypically normal male infant was delivered. This was not actually unexpected, since the initial abnormal complement was obtained from only one growth center in culture. This finding had thus been interpreted as a culture artifact, clonal in origin. The paucity of analyzable material occurred because only about 0.5 mg of villi were obtained, and these in very small fragments. Consequently, only one culture could be initiated, and only one center was analyzable. (4) The 46,XX,−13,+t(13q13q) complement was confirmed on abortus tissue. (5) The 46,XY/47,XY,+15 mosaicism was not confirmed at amniocentesis. The pregnancy continued, and a normal male infant was delivered. However, blood for cytogenetic confirmation has not yet been obtained. Interestingly, this mosaicism was confined to direct preparations. (6) A 45,X complement was observed in both direct preparations and in cultured cells. The same complement was confirmed in abortus material.

Overall then, we consider three abnormalities confirmed (Nos. 1, 4, and 6) and three not indicative of fetal anomalies (Nos. 2, 3, and 5).

Comment

The feasibility of routine cytogenetic evaluation of chorionic villi requires affirmative response to each of two general questions: (1) Do villi reflect fetal status, as opposed to being unrepresentative as the result of different embryonic origin? (2) Are villi obtained by aspiration of sufficient quality and quantity to render chromosomal analysis practical in a clinical setting? Early experiences of ourselves and others indicate that affirmative responses to both queries are likely. Notwithstanding our general optimism, however, several dilemmas must be resolved before chorionic villus sampling proves as reliable as amniocentesis for prenatal genetic diagnosis.

Maternal cell contamination is one possible dilemma, albeit one that can be minimized with experience. Maternal decidual tissue can be identified and excluded from preparations. The problem appears greatest in cultured preparations. Maternally derived decidua appear to undergo mitoses much more slowly than fetally derived villi, thus erroneously including maternal cells is unlikely to yield spurious results in direct preparations. In cultured preparations, maternal cells may grow and must be excluded before initiation. The one diagnostic error resulting from maternal cell contamination occurred in our early experience. We believe repetition would be rare at present.

That not all abnormal metaphases signify an abnormal infant is axiomatic in prenatal cytogenetic diagnosis. In chorionic villus sampling several special problems exist. First, relatively few cells may be available for analysis, and these cells may be derived from only a limited number of villi. Diagnostic errors caused by an abnormality restricted to a clone of cells are thus magnified. Second, clones of aneuploid or structurally abnormal cells may be especially troublesome in villi, which are not only rapidly dividing but not yet subject to the selective elimination that may occur later in pregnancy. We seek to resolve the inevitable diagnostic problems of chorionic villus sampling by initiating both direct as well as long-term (culture) preparations. Disagreements between results of direct preparations and results of cultures do arise. We thus developed and applied the following logic to determine our diagnosis:

1. Suppose one result is a male, and the other a female. The male complement is assumed to reflect fetal origin.

2. Suppose the complement is female, but results are only available from direct preparations and these are abnormal. This is considered likely to reflect fetal abnormalities. This type of preparation is less likely to show maternal contamination, especially if nonmosaic trisomy exists.

3. Suppose mosaicism occurs in both direct as well as cultured preparations. The mosaicism is then assumed truly to reflect fetal abnormalities; however, 45,X/46,XX or 45,X/46,XY mosaicism may still pose interpretive dilemmas even if there is "true" mosaicism by the operational definition.

4. Suppose mosaicism is detected only in direct preparations, but large numbers of cells (for example, 40 to 50) in cultured preparations show only a normal complement. Patients are informed of the disagreement, but the likelihood of a normal fetus is high. This approach is especially preferred if the chromosome involved is not one likely to be compatible with a live birth. Examples of "lethal" trisomies includes those for Nos. 2, 15, and 16.

5. Suppose mosaicism is found only in cultures. If possible, results are thus treated in similar fashion as that for interpretation of amniotic fluid cultures.[4] That is, true mosaicism is defined as requiring the same abnormality to be found in more than one culture or clone. Of course, if only one culture is available for chorionic villus sampling, as is often the case, the operational definition of pseudomosaicism (that is, confirmed to one culture) cannot always not be applied. In such a situation, counseling will depend on the total number of analyzable cells from direct and culture preparations, the number of growth centers, and the chromosome involved (see 4). If the abnormal complement can be demonstrated in several growth centers of one culture, true mosaicism is more likely.

Applying these and other conventional cytogenetic criteria led us to conclude that three of the six abnormalities we observed (Table II) were in fact truly reflective of fetal status. Three others probably reflected in vitro aberrations or clonal abnormalities restricted to certain villi. Many investigators attach less significance if mosaicism is confined to cultures, but we observed abnormalities apparently not reflective of fetal status in direct but not long-term cultures (case 6, Table II). Especially noteworthy was our failure to confirm

Table IV. Unbalanced translocations*

45,X/46,XX mosaicism that fulfilled criteria established for amniotic fluid analysis, namely, presence of the abnormality in more than one flask or clone. We now believe 45,X cells to be especially common in villi, and we liberally recommend confirmatory amniocentesis whenever 45,X/46,XX or 45,X/46,XY mosaicism is detected. This same reasoning holds when we detect a trisomy for an autosome lethal in triplicate (for example, Nos. 2, 5, and 16). Criteria for interpreting confirmatory amniocentesis are those published previously,[5] irrespective of previous chorionic villus sampling results.

Even after excluding chromosomal aberrations not reflective of fetal status, the proportion of abnormalities in chorionic villus sampling will remain relatively high. Our own data are limited, but Tables IIIA and IIIB show outcome of chorionic villus sampling in a European Collaborative Series. The proportion of aneuploid fetuses in chorionic villus sampling is 4.7% between maternal ages 35 to 39, and 9.2% over age 39. The proportion of abnormalities in amniocentesis is much lower, namely, only slightly (1.5×) higher than the well-known frequencies observed in live-born infants.[6] Aneuploidy in chorionic villus sampling is also greater at 8 weeks than at 10 or 11 weeks (Table IIIB). Table IV shows frequencies of unbalanced offspring conceived by parents with a balanced translocation; frequencies are much higher in chorionic villus sampling than amniocentesis, and these frequencies approach theoretical expectations. All the above emphasize that chorionic villus sampling is occurring before selective processes that are not completely finished by time of amniocentesis.

None of the dilemmas considered above diminish our general enthusiasm for chorionic villus sampling; they merely point out that it remains investigational. Increasing experience will surely show trends that will continue to make interpretative dilemmas less common. Indeed, one must recall that pseudomosaicism occurs in 1% to 3% of amnniotic fluid analyses, but true mosaicism in only 0.1 to 0.2%.[6] Tetraploidy is now recognized as a normal phenomenon in amniotic fluid cultures, but this was once considered a dilemma. We suspect that the frequency of true mosaicism may prove more common in amniotic fluid cultures than in chorionic villus sampling, yet not so frequently as to pose insurmountable diagnostic problems. Liberal use of confirmatory amniocentesis is recommended while investigations continue to define the accuracy and reliability of chorionic villus sampling.

Discussion

Dr. Federico G. Mariona, Detroit, Michigan. This report by the Northwestern Memorial Hospital group reiterates their cautious and positive approach to the use of chorionic villus sampling in first-trimester genetic diagnosis. The fact that only 188 patients have been screened in over 1 year of clinical service demonstrates a seemingly nonaggressive counseling approach. Twenty-two percent of the patients were classified ineligible for chorionic villus sampling, and 26% of the remaining patients declined having the procedure performed. We can possibly contribute their technical success and low number of procedurally related losses to this stringent patient screening program. Their careful attention to patient selection can further by evidenced by the fact that the majority of patients were sampled between 9 and 10 weeks, with no patients being included after 11 weeks' gestation. This cautious attitude contributes to a laudable policy when we consider the self-imposed anxiety and pressure of some physician groups to accumulate cases. Generally speaking, their selection and exclusion criteria can be construed as being standard.

We use a somewhat different catheter, which I no longer trim as I did during the experimental phase. The stylet is round ended and malleable and protrudes half a millimeter beyond the blunt end of a 21 or 26 cm, 1.2 mm outer-diameter Teflon catheter. This catheter is under an investigational device exemption from the Food and Drug Administration. The catheter used by the authors of this paper is twice as thick. I am curious to know what prompted their decision to select that particular catheter.

I noted that one of the diagnostic errors was related to the obtainment of an extremely small sample despite catheter size. Have you correlated the size of your samples with that of other groups using a smaller catheter or with those of your two obstetricians using different-sized catheters? My samples have gone from 0 (one case, 1.6%) to >50 mg, and one pass was sufficient in 73% of the cases.

Our standard protocol for follow-up of all sampled

patients includes a repeat ultrasound scan between 16 and 19 weeks' gestation, with concomitant obtainment of a sample of maternal serum α-fetoprotein. To date, we have not found a correlation between sample size, number of passes, and hypoechoic placental areas. Further, despite the significant increase in presample and postsample maternal serum α-fetoprotein, we still have not demonstrated a significant difference on the 16-and 19-week maternal serum α-fetoprotein reports between instrumented patients and noninstrumented patients. Have you monitored any of these parameters?

This study reports one procedurally related loss in a patient for whom two passes were needed; an adequate sample size was obtained as well as a normal complement, but she bled vaginally. Postsampling vaginal spotting has occurred in 9.6% of our patients sampled to date. Have you looked at the frequency of this event in your population?

The authors make a careful evaluation of the laboratory vagaries of their first 103 samples. I shall not attempt to verbally review their technical comments; however, I want to reference their efforts to establish formal recommendations for those involved in the cytogenetic analysis of complements from chorionic villi. Despite their stringent guidelines, they report one error in the sex determination, and six discrepancies, three of which were not confirmed.

The diagnostic disparities deserve special consideration, since 50% nonconfirmatory results justify fully the statement that chorionic villus sampling remains an investigational technique. Three of the six disparities were taken to confirmatory amniocentesis; however, two chorionic villus sampling complements were not confirmed by amniocentesis. A 45,X complement was confirmed by amniocentesis, and I am wondering, What was the parental decision? With reference to the nonconfirmatory abortion tissue complement, was this abortion spontaneous or requested on the basis of chorionic villus sampling direct and long-term cultures?

Based on the success rate of our short-term cultures, we stopped performing long-term cultures on a routine basis unless an abnormal complement was noted on the direct preparations. The latter has occurred in nine of our cases (14%).

In considering the vagaries of the cytogenetic interpretations, the authors have developed a "response protocol" for abnormal findings. This deserves emphasis and appropriate consideration, since it is only through caution and experience that this process will not increase the existing level of parental anxiety.

I am certainly interested in clinical details concerning the nine patients who opted for backup amniocentesis after a 46,XX complement was reported on chorionic villi. In our experience the perpetuation of the anxiety and emotional problems becomes a serious situation as the weeks go by.

It is clear to this reviewer that the authors' aim is to call attention to the fact that chorionic villus sampling as a first-trimester fetal diagnostic technique remains in the investigational phase. Certainly the need exists to continue assessing the risks and accuracy of chorionic villus sampling compared with that of the amniocentesis, which is the established technique.

Authors' note: Dr. Mariona has misunderstood our results. There were six abnormal complements detected. Four of these were considered reflective of the fetal complement: 45,X; 47,XY, +13; 45,X/46,XX; and 46,XX,t(13q13q) [Table I]. Three of these four were confirmed; one was not (45,X/46,XX). The other two abnormalties were suspect; consequently amniocentesis was recommended. The 45, XY,t(4;15) was in only one clone because of the extremely small amount of tissue received (0.05 mg). The other case was mosaic in direct preparations and normal in cultures, the mosaicism for a lethal chromosome, No. 15. Expectation of normal complements was confirmed at both amniocentesis and delivery.

Dr. James E. Nickel, Helena, Montana. Since the review of Rodeck[1] in 1983 in which he described the five biopsy techniques, one other technique has been added. Of these six techniques, the authors have chosen in their first paper to use the technique of guided catheter insertion with ultrasonic sector scanning. For a successful biopsy, three factors must be accomplished: yield of fetal tissue should be reliable, it should not be contaminated by maternal tissue, and there should be minimal risk to the mother and the fetus.

The complication rate of this surgery is defined as the number of patients in whom the procedures failed or was thought to cause ill effects to the patient or the pregnancy, either immediately or in the initial follow-up. In a survey of the literature of the complication, rates have run from 0% to 67%, but in larger series and after a number of cases for operator experience, the complication rate seems to be approximately 2%. After an average number of cases, approximately 70, the complication rate drops from 6% to a 2%. In the large series of cases as reported by these authors and a series of other authors and from the international studies, it is now believed that the fetal mortality rate will not be much increased over that which is reported.

One concern is the percentage of patients who bleed after this operation, which is believed to be 14%. This percentage was not reported by the authors, and we would like to ask what percentage of patients bleed following their procedures. It is thought by some authors that a number of complications occur with an increased number of repeated insertions of the catheter, these being related to bleeding, leaking of amniotic fluid, and abruptio placentae. Of major concern in this technnique is that of evaluation of sepsis. As reported in the *Chorionic Villus Biopsy Newsletter,* there are now a number of cases of sepsis with serious complications. I would ask the authors what the percentage of their infection rate is and whether they are currently doing cervical cultures.

A further concern, which is currently being answered by the authors, is that if bacterial invasion does occur at the biopsy site, is the potential of weakening of the amniotic membranes a related problem in the ongoing

series? Have they, since the initial gathering of these data, noticed any increased rate of premature rupture of the membranes?

It is noted in the paper that the risk of teratogenesis is low, since organogenesis is nearly completed by 8 weeks and their biopsies are apparenntly being done after 8 weeks. The risk of fetal malformation in this series is very low, and I wonder whether the authors have noticed, in other series in which the insertions were accomplished before 8 weeks, an increased rate of teratogenesis.

The paper of Warren,[2] in *Lancet* revealed that in approximately 49% of all cases having chorionic villus biopsy, maternal hemorrhage occurs. Do the authors use or plan on using tests such as the Kleihauer-Betke test to determine whether fetal/maternal hemorrhage has occurred?

The study by Perry[3] in 1985 reported experience similar to that of the authors, with a success rate of 93% and the only immediate complication occurring in approximately 5% of their cases. They were the first to report on patient attitudes toward this technique. It was found in their paper that an equal number of patients preferred chorionic villus biopsies as compared to amniocentesis. However, if it were known that a less than 5% complication rate occurred, then over 70% of patients were found to prefer chorionic villus biopsy. In the summary of their paper their studies revealed that chorionic villus biopsy was not universally accepted because of the 5% complication rate. I would ask the authors whether in their presurgical counseling they suggest a <5% complication rate and whether this was a major factor in the decision of 38 patients who elected not to have chorionic villus biopsy, as noted in the authors' summary table.

It was found in review of the literature at the end of 1984 that 43 centers had reported an excess of 3000 cases with a 97% success rate. The total chorionic villus biopsy fetal loss rate was 4.1%, and it was found that centers with the most experience had a fetal loss rate of 3.4%. It is suggested that the advantage of the chorionic villus biopsy is a possible reduction in the emotional and physical distress of reproduction for couples at genetic risk because of the ease of performing it in the first trimester. However, current concern is (1) that chorionic villus biopsy is more costly than amniocentesis, (2) that it takes longer to accomplish this technique, and (3) that it requires a higher level of ultrasound input. The preparation of the villi for cultures takes longer, and the direct preparations are labor intensive, requiring a much higher level of skill in the team. Have the authors currently evaluated the cost-effectiveness of this study and do the authors have suggestions as to what legal precautions we may take in freeing ourselves of the potential liability of this technique?

In their second paper the authors have explained the use of the technique of dissecting microscope and direct preparation, as well as cultured villi. This represents a shortened version of the report of Holzgreve[4] of the University of California in San Francisco in which three different methods of chromosome analysis are used. The authors have shown a marked improvement in their technique because even with use of this technique Martinville et al.[5] had reported 9% failures of cultured tissue. As can be seen from the paper the results of this technnique rely entirely upon the purity of villus tissue. In a report of possible sources of error Ridler[6] indicated that the prenatal diagnosis by means of chorionic villus sampling has not yet fulfilled its early promise. This was because of the variable success in attaining villi pure enough for culture, and because in direct preparation for karyotyping with the chorionic biopsy, the likelihood of contamination with maternal cells is much greater. It was thought by these authors that artificial mosaicism is much more common in trophoblastic tissue rather than fetal tissue, and herein may lie the possibility of the error. This point has been clearly brought up and discussed by the authors.

In the excellent summary by Blakemore[7] in 1984, with use of a modification of the Niazi culturing techniques for obtaining metaphase cells and the use of quinacrine-banded karyotypes, the results could be obtained in 5 hours from uncultured villus. The authors have not reported to us regarding the time interval for initial diagnosis. It was in the summary in Blakemore's paper that they indicated that their technique did show a high degree of reliability; however, it was felt by these authors that at the current time they were spending one and a half to two times the effort and resources used in chorionic villus biopsy compared to that for chromosomal diagnosis. I would ask the authors whether they have done a cost-analysis comparison between this technique and routine amniocentesis techniques. Do the authors feel they would have a higher failure rate currently with their techniques of villus samples that were <5 mg? Of concern to all people using this technique is the significance of mosaicism and polyploidy, which needs to be established in direct preparations and harvest of cells. It is well known that the amniocytes demonstrate a high frequency of tetraploidy, which is of no recognized significance itself, and this has been reported on numerous occasions in animal studies.

I would like to ask the authors whether they are planning an ongoing comparison study with early prenatal karyotyping done simultaneously from blood samples to establish the reliability of this technique concurrently with their technique. I would also like to ask the authors about the number of technicians required in their approach, the time required in preparations, and the length of time between the biopsy and the laboratory diagnosis.

The authors have presented a very comprehensive plan to evaluate the samples if they get questionable results on direct preparation and should be complimented on this approach. If the authors do not get enough tissue, do they eliminate the direct preparation and go directly to use of the cultures?

I would like to thank the authors for supplying me

with a summary outline of their papers before the time of the meeting and would like to compliment them for their ongoing work in what is considered at this point an alternate technique to amniocentesis. Also, I would like to ask the authors how they currently handle the liability situation, which must arise with use of this experimental technique.

DR. ROBERT CARPENTER, Houston, Texas. One point raised by Dr. Mariona that Dr. Simpson might discuss really needs a lot of emphasis, and that is the aspect of counseling. The question was raised by him as to the number of patients who subsequently elect not to have chorionic villus sampling done. We have had 100 procedures done in our center, and at least 50% to 60% of the patients who requested the procedure did not have it done. The reasons for this are very diverse, but I think the major one is that aspect raised by Dr. Nickel, that is, what is the loss rate associated with the procedure. Couples fear that they may experience a loss due to chorionic villus sampling even when the data for an individual center show a loss rate of 2%.

In our particular center the loss rate associated with the procedure that is quoted to patients is the loss rate experienced in 9000 worldwide series of about 4%. We have had five losses in our 100 procedures. To date, those five losses have occurred from 3 days to 7 weeks after the procedure. So far we have not had preterm labor in any of the patients at more than 21 weeks' gestation.

Therefore the critical questions of loss rate and infection are also addressed and are extensively handled in our counseling sessions. The risk of infection is the one risk we cannot quantitate, and there have been relatively few cases in the 9000 procedures that have been done.

Those two particular issues, when raised, will scare many patients, and I think it is very appropriate in any counseling center dealing with chorionic villus sampling that those two issues be emphasized and emphasized again. We are probably overly counseling, and in effect, instead of being nondirective, we are being biased to a more directive conservative view.

All of the other things discussed by Dr. Elias as far as procedural techniques are concerned should be done to minimize the risk of infection.

One other question was raised concerning cervical cultures. We are doing cultures in all cases at the time of chorionic villus sampling. We currently have a continuous series of 60. We are finding a significant culture-positive rate for both mycoplasma and for *Ureaplasma,* and also we are establishing cultures from the catheter on its removal from the uterine cavity. We are also finding similar organisms as well as other organisms, including *E. coli* and group B streptococci, which did not show up on the initial culture. The meaning of that information will be seen in the future as more prospective data are collected.

DR. C. BRANDON CHENAULT San Antonio, Texas. Has consideration been given to Rh sensitization? What do you do about it as far as counseling and treatment are concerned?

DR. ELIAS (Closing). Let me begin by addressing the question of vaginal bleeding. We have followed up all of our patients very carefully and have found that about half of them had some spotting within 48 hours after the procedure. On follow-up the vast majority reflected some old blood in the vaginal vault from the site of the tenaculum grasping.

With respect to infection, we have not had any in our series to date. We routinely perform cultures for gonorrhea as a screening process, in accordance with the National Institutes of Health protocol, and we have not found any to be positive yet. We do not perform cultures for other organisms because at this time we are not sure about the significance of the inevitable cadre of organisms that one could find.

We recognize that there is a very significant potential for sepsis in these patients and we have alerted all of our physicians about this risk. We have sent out a special letter to this effect. In addition, we give our patients a handout to take home with them, which specifically discusses the warning signs and gives them telephone numbers to call in case of suspected problems. We follow up all of our patients 3 to 4 days after the procedure to find out if there have been any untoward effects.

With respect to the issue of premature rupture of the membranes, we did have one case that I discussed in the presentation. This patient had premature rupture of the membranes at 27 weeks' gestation and was delivered at 29 weeks' gestation with the infant dying of β-hemolytic streptococcal pneumonia. This is one of the major focuses of the National Institutes of Health collaborative study, and the answer to the problem of premature rupture of the membranes will hopefully be forthcoming. From personal communications with some of the other centers, we have some concerns about second-trimester rupture of the membranes associated

with oligohydramnios, and we will have to keep a very close watch on this possible association.

With respect to Rh sensitization, at the American Society of Human Genetics meeting in Salt Lake City, Utah, Dr. Karen Blakemore and her colleagues from Yale reported a study in which maternal serum α-fetoprotein levels were assessed both before and after chorionic villus sampling in 51 cases, and in 32 cases they found increases of ≥5 ng/ml. That means that in two-thirds of the cases there was some degree of fetomaternal bleeding. There was also a positive correlation with the amount of villi that were aspirated and the level of fetoprotein. We routinely administer Rh immune globulin after chorionic villus sampling to all appropriate Rh-negative candidates.

The acceptance of chorionic villus sampling is, of course, a very complex issue. We and others are currently collaborating on psychological profile studies trying to assess the various anxieties that patients undergo in making decisions between no prenatal diagnosis, chorionic villus sampling or amniocentesis. Obviously proper counseling in a neutral fashion is critical.

A question was asked concerning the cost of the procedure. We can say it is essentially the same as for a genetic amniocentesis at our institution. We do, however, add about $200 to the procedure for the ambulatory surgery suite as well as for the postoperative follow-up, which is about 45 minutes.

Legal precautions in chorionic villus sampling are germane in the context of developing a new surgical technique. We can only say that we feel it is very important to have institutional review board approval of this new procedure because, as we have tried to indicate, both the safety and the accuracy have not yet been fully delineated. We believe that before proceeding to use chorionic villus sampling in continuing pregnancies it is required to have Food and Drug Administration approval for the catheter to be used. One does not want to be caught in a situation of having a complication when the Food and Drug Administration has specifically said that only approved centers should be doing the procedure. The most important "legal precaution" is that one ought to fully adhere to the spirit as well as the letter of informed consent, and I believe that good medicine will result in good legal outcomes.

The time for results generally takes about 48 hours with direct analysis and 5 to 7 days thereafter for the cultures. Initially we found our laboratory processes to be very labor intensive, but more recently we have actually found that the time per technician is reduced because of the advantage of not having to follow cultures for prolonged periods of time. Currently we feel that a cytogenetics technician can process approximately 150 samples per year.

The question was asked whether we were doing any work with peripheral maternal blood or trophoblastic cytogenetic analysis. We have initiated a collaborative effort with Dr. Harold Miller at Michigan State University, and of course we all have hopes of developing noninvasive methods for prenatal monitoring.

If a small amount of tissue is obtained at chorionic villus sampling, as Dr. Simpson indicated, we would generally process the specimen by the culture technique because this offers a greater number of metaphases. However, each case must be individualized.

With respect to Dr. Carpenter's comment about counseling, this is obviously crucial. We would much rather have a patient decline chorionic villus sampling than have a patient agree to it who is not fully committed to the process. Our genetic counselor spends approximately 45 minutes with each couple, and we follow this up by an additional 10 to 15 minutes of discussion before the procedure.

We have also found, as others have, that the optimal time of sampling is between 9 and 11 weeks from the onset of the last menses. At less than 8 weeks one begins to have trouble documenting fetal compromise. More important, there is a very dramatic drop-off rate in the frequency of cytogenetic abnormalities after this time. In other words, if you were to sample at 6 to 7 weeks you would be ascertaining a greater number of chromosomally abnormal fetuses that would have otherwise spontaneously aborted.

Finally, in evaluating various catheters in our initial trials, we determined that samples can be more reliably obtained with the larger-sized catheter (that is, 16 gauge outer diameter).

Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women

Charles M. Stedman, M.D., Judy C. Baudin, M.T.(A.S.C.P.), S.B.B., Charles A. White, M.D., and E. Shannon Cooper, M.D.

New Orleans, Louisiana

The possibility of Rh immune globulin failure exists when a fetomaternal hemorrhage exceeds 25 to 30 ml of whole blood and only one 300 μg vial of Rh immune globulin is administered. In this prospective study of 1000 consecutive Rh-negative women who were delivered of Rh-positive newborn infants, the presence of fetal erythrocytes in maternal blood was identified with use of both the D^u test read microscopically and the erythrocyte rosette test. All positive tests prompted fetomaternal hemorrhage quantification with use of a modified Kleihauer-Betke acid elution test. Nineteen patients demonstrated a positive rosette test, and the only positive D^u tests were in five of these 19. Six of the nineteen had levels of >30 ml of whole blood for an incidence of 0.6% for fetomaternal hemorrhage exceeding the protective capabilities of the standard Rh immune globulin dosage. In experiments with simulated fetomaternal hemorrhage, all 79 samples, containing from 2.5 to 70 ml of fetal whole blood, were positive according to the erythrocyte rosette test. Applying the D^u test to the same samples resulted in a 30% false negative rate at the level of a 30 ml simulated hemorrhage. Based on sufficient sensitivity, ease of interpretation, and reasonable cost, the rosette test appears to be a superior screening test for excessive fetomaternal hemorrhage in Rh immune globulin candidates. (Am J Obstet Gynecol 1986;154:1363-9.)

Key words: Erythrocyte rosette test, Kleihauer-Betke test, Rh immune globulin, fetomaternal hemorrhage

Administration of 300 μg of Rh immune globulin after delivery prevents Rh isoimmunization in over 98% of cases.[1-3] Despite a program of routine postpartum use of Rh immune globulin, sensitization can occur if fetomaternal hemorrhage sufficiently antedates delivery or if the amount of Rh immune globulin is inadequate to suppress the antigenic effect of a large fetomaternal hemorrhage. Bowman and Pollock[4] have shown that antepartum administration of 300 μg of Rh immune globulin at 28 weeks can reduce the incidence of the former from 1.8% to 0.07%. Nevertheless, despite use of a combination of antepartum and postpartum Rh immune globulin, cases of quantitative failure remain a possibility unless routine postpartum screening by means of a sensitive test for fetomaternal hemorrhage is used.

A 300 μg vial of Rh immune globulin contains sufficient antibody to suppress the immunogenicity of 15 ml of Rh-positive fetal red cells or 30 ml of whole blood.[5] Although the incidence of postpartum fetomaternal hemorrhage in excess of 30 ml of whole blood has been reported to be only 0.2 to 1.0%,[6-7] this subgroup of patients must be identified so that additional Rh immune globulin can be offered. Currently available tests to identify excessive fetomaternal hemorrhage include modified Kleihauer-Betke acid elution techniques, the D^u test read microscopically, erythrocyte rosette techniques, and enzyme-linked antiglobulin tests.[8] Factors such as cost, laboratory time required to complete the test, and ease in interpretation have led to use of the D^u test or rosette test during the past 5 years by a majority of laboratories where fetomaternal hemorrhage screening has been performed.[9, 10]

The purpose of this study was to screen consecutive Rh immune globulin candidates with the D^u test and the erythrocyte rosette test in parallel. In addition, both techniques were applied to mixtures of blood containing measured proportions of Rh-positive fetal cells and Rh-negative adult cells.

Material and methods

For a period fo 30 months, postpartum blood samples from 1000 consecutive Rh-negative mothers who delivered Rh-positive infants were collected in glass tubes containing ethylenediaminetetraacetate at four hospitals participating in the study. Samples were screened for fetomaternal hemorrhage at a single hospital with use of both the microscopic D^u test and the rosette test. Quantitation of the amount of fetomaternal hemor-

rhage of clinical samples that demonstrated a positive test result was determined. The method used was a modification of the Kleihauer-Betke acid elution test[11] and utilized a fetal cell staining kit (Simmler, Inc., St. Louis, Missouri). The directions of the manufacturer were followed.

In the D^u test, one drop of commercially available, chemically modified IgG anti-D was placed in a 12 × 75 mm glass tube. One drop of a once-washed 5% saline suspension of test red cells was added. The tube containing red cells and antiserum was incubated at 37° C for 15 to 20 minutes, followed by four automated saline washes to remove unbound anti-D. Two drops of commercially available, anti-IgG antiglobulin were added to the gently resuspended washed cell button. The tube was centrifuged in a tabletop centrifuge for 15 seconds at 3500 rpm. The cell button was gently resuspended, and numerous fields were examined microscopically under low power (×100). A test was interpreted as positive when agglutination was observed in any of the fields examined. The D^u test required approximately 25 minutes for completion.

In the rosette test, one drop of commercially available, chemically modified, IgG anti-D was added to a 12 × 75 mm glass tube. One drop of a once-washed 5% saline suspension of test red cells was added. The tube containing red cells and antiserum was incubated at 37° for 15 to 20 minutes, followed by four automated saline washes to remove unbound anti-D. Indicator cells were prepared by diluting commercially available, ficinized, Rh-positive (cDE) red cells. One drop of the 0.5% saline suspension of enzyme-treated Rh-positive (cDE) indicator cells was added to the resuspended washed button. The tube was immediately centrifuged in a tabletop centrifuge for 15 seconds at 3500 rpm. The cell button was resuspended, and numerous fields were examined microscopically under low power (×100). At least 10 random low-power fields were examined. A test was interpreted as positive when rosettes were present (see Fig. 1). A negative test had no rosettes and an even field of unagglutinated cells. Positive and negative controls were tested with each run of test samples. Positive controls consisted of 0.5% (CcDe) erythrocytes and 99.5% (ce) erythrocytes. Rh-negative red blood cells were used as the negative control. The rosette test required approximately 25 minutes for completion.

Group O negative (ce) adult red cells and group O positive (CcDe) cord cells were washed four times in normal saline solution. A hematocrit was performed on each sample and adjusted to be within 1% of each other. Mixtures were prepared volumetrically to yield fetal-to-maternal red cell ratios of 1.4%, 1.0%, 0.8%, 0.6%, 0.4%, 0.2%, 0.1%, 0.05%, and 0%. These mixtures were prepared to simulate blood samples from Rh-negative mothers with fetomaternal hemorrhage of 70, 50, 40, 30, 20, 10, 5, 2.5, and 0 ml whole blood, as calculated by the Kleihauer formula. These mixtures were aliquoted to prepare 100 coded samples by a technologist not directly involved in the study. One technologist (J. C. B.) tested all artificial mixtures as unknowns, using both the microscopic D^u test and the rosette test. All samples were tested within 72 hours of preparation.

The hospital records of all patients with either a positive D^u test or positive rosette test were reviewed by one of the authors for mode of delivery and complications of pregnancy.

Results

Of 1000 consecutive Rh-negative patients who were delivered of Rh-positive infants, 19 demonstrated a positive rosette test (Table I). Based on six of the 19

exceeding a 30 ml fetomaternal hemorrhage when quantitated with the Simmler fetal cell stain, the calculated incidence of fetomaternal hemorrhage requiring >300 μg of Rh immune globulin is 0.6%. The only positive D^u tests were in five of these 19. No sample was positive with the D^u method and negative with the rosette test. Nine of 19 (47%) were delivered by cesarean section, and 10 of 19 (53%) experienced normal labor and a vaginal delivery. Manual extraction of the placenta was performed at all nine cesarean sections.

Rosette tests on artificial mixtures containing fetal erythrocytes were positive in all 79 samples, with the calculated fetomaternal hemorrhage ranging from 2.5 to 70 ml of whole blood (Table II). One sample of 1.0% fetal cells had to be discarded because of contamination. Use of the D^u test resulted in a 30% false negative rate for a fetomaternal hemorrhage of 30 ml. At all eight concentrations of fetal cells, the rosette test was more sensitive than the D^u test. With use of a two-sided sign test for nonparametric data, the rosette test was found to be superior to the D^u test with a calculated p value of 0.0078. None of the 20 specimens containing only adult erythrocytes was positive by means of either the D^u test or rosette test.

Reagent cost added to the cost of the technologist's technical time of approximately 25 minutes yielded a laboratory cost of $6 to $7 per test for both the rosette and D^u technique. Based on 40 minutes of technical time, similar calculations produced a laboratory cost of $9 to $10 for each test by means of the Simmler fetal stain.

Comment

The presence of fetal red blood cells in the maternal circulation was first demonstrated in 1954 by Chown,[12] who agglutinated Rh-positive fetal erythrocytes in a postpartum maternal blood sample of an Rh-negative patient. In 1957 Kleihauer et al.[11] described the first test allowing differentiation of fetal erythrocytes from adult erythrocytes. They showed that at an acid pH

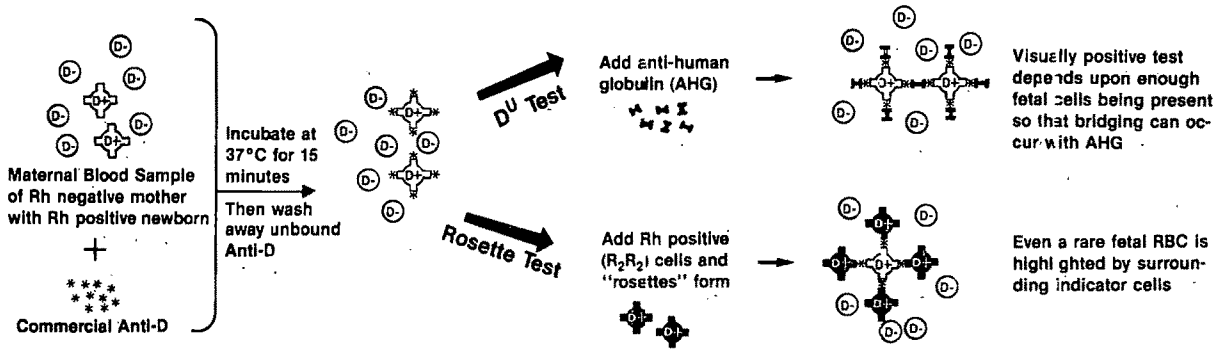

Fig. 2. Diagrammatic representation of the microscopic D^u test and erythrocyte rosette test.

level, hemoglobin A can be eluted from red blood cells whereas hemoglobin F is more resistent to elution and can be identified by special stain uptake.

Despite being the technique most frequently used in previous clinical studies of fetomaternal hemorrhage, several aspects of the Kleihauer-Betke test have discouraged routine use as a screening test. The reagents require fresh preparation, and the pH of the elution must be strictly maintained. An acid elution kit (Fetaldex, Ortho Diagnostics, Inc., Raritan, New Jersey) was introduced in 1975 as a proposed improvement over the Kleihauer-Betke method. The Fetaldex kit provided prepackaged, premeasured reagents and therefore was convenient and technically easier to use. Drawbacks to acid elution testing of all Rh negative parturients continued to include cost, time of laboratory processing, and false positive tests. Depending on the racial composition of a patient population, false positive acid elution tests can occur in 2% to 6% of individuals with hemoglobinopathies or significant elevation of hemoglobin F. Pembrey et al.[13] have reported that 6% of nonpregnant female controls manifested hemoglobin F concentrations >0.9%, a level at which all samples had positive cells on acid elution preparation.

By 1979 the most commonly used fetomaternal hemorrhage screening test was the D^u test read microscopically.[9] The term "microscopic D^u" refers to examination of a maternal blood sample with use of the antiglobulin test after incubation with incomplete anti-D typing serum (see Fig. 2). Advantages of this test include low cost as well as ease of completion in the laboratory. The major disadvantage of the D^u test is the 12% to 17% false negative rate noted in large series[10] for a simulated fetomaternal hemorrhage of 30 ml (see Table II). Our data highlight this weakness with the finding of a 30% false negative rate for a simulated 30 ml fetomaternal hemorrhage. Also of concern is the fact that the D^u test in our study yielded false negative results even for simulated fetomaternal hemorrhage >30 ml. False negative findings, of course, allow the possibility of undertreatment of the Rh immune globulin candidates.

In 1982 Sebring and Polesky[7] suggested a rapid erythrocyte rosette technique as a screening test for significant fetomaternal hemorrhage. This test differs from the D^u test at the point of the last step (see Fig. 2). Instead of adding anti-human globulin, the rosette test consists of adding enzyme-treated Rh-positive (R_2R_2) erythrocytes. Even a rare fetal erythrocyte is highlighted by surrounding indicator cells whereas the D^u test requires fetal cells to be close enough that bridging with anti-human globulin can occur. Positive rosette tests are visually striking (see Fig. 1) even to the neophyte in the laboratory. In the 1982 study of Sebring and Polesky, prepared mixtures of Rh positive fetal cells and Rh negative maternal cells were screened by means of the microscopic D^u test and rosette test. At the level of a 30 ml fetomaternal hemorrhage, the sensitivity of the rosette test was found to be 100% and the sensitivity of the D^u test to be 85%. The rosette test was recommended as the screening test of choice for fetomaternal hemorrhage.

Recently reported, fluorescence-activated cell sorter techniques[14] have suggested that fetomaternal hemorrhage at delivery is a universal event. Medearis and associates reported that the mean volume of fetal erythrocytes was 0.156 ml based on a mean Rh-positive to Rh-negative erythrocyte ratio of 1:14,100 in maternal blood. Obviously the ideal screening test would be negative for all instances of insignificant fetomaternal hemorrhage yet would be positive for all hemorrhages exceeding the protective capability of the usual postpartum dosage of Rh immune globulin.

Our findings indicate that within our population, 19 per thousand Rh immune globulin candidates have a positive rosette test and approximately 6 per thousand demonstrate fetomaternal hemorrhage in excess of 30 ml. Cost and laboratory technical hours necessitated by quantitation of only 19 tests per thousand represents minimal inconvenience for a screening test that is 100% sensitive at levels well below the critical level of a 30 ml fetomaternal hemorrhage. False positive results by means of the rosette test can occur as has already been reported by Taswell and Reisner,[15] who found a 1.5%

false positive rate among 240 blood samples containing only Rh-negative adult erythrocytes.

Because the majority of excessive fetomaternal hemorrhages cannot be predicted by obstetric events (see Table I), a screening test should be applied to the entire population at risk. Since 1981, routine screening of all Rh immune globulin candidates for excessive fetomaternal hemorrhage has been a standard of the American Association of Blood Banks[16]; subsequently, the choice of screening test rather than whether to screen has been the main subject of debate. Based on sufficient sensitivity, ease of interpretation, and reasonable cost, the erythrocyte rosette test appears to be a superior screening test for excessive fetomaternal hemorrhage in Rh immune globulin candidates. Because the rosette test demonstrates 100% sensitivity for a 10 ml fetomaternal hemorrhage in our series as well as in previous reports,[7, 15] it may also prove to be the test of choice in countries where routine postpartum treatment consists of 100 to 125 μg of Rh immune globulin.

We are most grateful to the following technologists and physicians who supplied blood samples for this study: Doris Ratcliff, M.T.(A.S.C.P.), S.B.B., and Leslie R. Bryant, M.D., at Southern Baptist Hospital Blood Bank, New Orleans, Louisiana; Rita Dyer, M.T.(A.S.C.P.), S.B.B., and Stephen T. Kraus, M.D., at Lakeside Hospital Blood Bank, Metairie, Louisiana; Melanie Positerry, M.T.(A.S.C.P.), Donna Chaisson, M.T.(A.S.C.P.), and Deborah Stalling, M.T.(A.S.C.P.), at Southeast Louisiana Medical Center Blood Bank, Houma, Louisiana.

Discussion

Dr. Neil K. Kochenour, Salt Lake City, Utah. Dr. Stedman has presented a convincing case for the use of the rosette test rather than the D^u test to detect fetomaternal hemorrhage. The rosette test was sensitive enough to detect all clinically important fetomaternal hemorrhages without a large number of false positive tests.

The authors state that "the choice of screening test rather than whether to screen has been the main subject of debate." In my opinion, it is still controversial whether or not all Rh-negative women who deliver Rh-positive infants should have a test for excess fetomaternal hemorrhage. The American College of Obstetricians and Gynecologists technical bulletin No. 79, August 1984, states "Routine screening is not recommended. The volume of fetal blood entering the maternal circulation should be determined, however, for all high-risk pregnancies."[1] Although some authors have found certain obstetric manipulations to be associated with a large fetomaternal hemorrhage, the authors of this study did not find this to be true. In a study of over 1200 Rh-negative women delivering Rh-positive infants, we found no correlation between excess fetomaternal hemorrhage and any obstetric manipulation except for manual removal of the placenta.[2] Thus it is not possible to identify reliably all patients at risk by screening "high-risk" patients.

In a cost-conscious medical environment, one reason for not recommending routine screening for excess fetomaternal hemorrhage may be the question of cost-effectiveness. I would like to briefly address that issue. I recently contacted nine hospitals of varying size throughout the state of Utah. Eight of the nine hospitals routinely screened the appropriate patients. The cost to the patient varied from $11 to $27. By means of these figures the cost-effectiveness of routine screening can be estimated; by means of the least expensive cost to the patient, the cost of screening 1000 patients is $11,000. Approximately 18 patients will require a Kleihauer-Betke stain to quantify the hemorrhage: a cost of about $300. Six of these will be found to have an excess fetomaternal hemorrhage requiring extra Rh

Table I. Cost of screening for excess fetomaternal hemorrhage

Erythrocyte rosette test	
1000 patients at $11	$11,000
19 Kleihauer-Betke stains for positive test at $17	300
6 additional Rh immune globulin treatments at $60	360
	$11,360
Cost per sensitization prevented (assuming four patients sensitized)	$ 3,000
Kleihauer-Betke modification	
1000 patients at $17	$17,000
12 additional Rh immune globulin treatments $60	720
	$17,720
Cost per sensitization prevented	$ 4,000

immune globulin at a cost of $60 per dose. The total cost of the screening procedure is about $11,660. If one assumes that four of these patients would have been sensitized had the excess hemorrhage not been identified, the cost per sensitization prevented is about $3000 (see Table I).

Four of the nine hospitals I contacted use a modification of the Kleihauer-Betke stain. The least expensive charge to the patient for this type of test in the hospitals that I contacted is $17. The cost of screening 1000 women with this type of program is $17,000. Twelve additional doses of Rh immune globulin would be required. The cost per sensitization prevented with this method is more than $4000. I would point out that the costs used in these examples may vary with the number of tests performed, since some kits have reagents that are useful for a limited time. Also, the cost of the kits may vary with the quantity purchased.

We can compare these costs with the cost of caring for an isoimmunized pregnancy. Again, I have made some assumptions about the severity of the involvement, but I believe this comparison at least gives some idea of cost-effectiveness. The isoimmunized patient requires amniotic fluid analysis during her pregnancy—in this instance, four amniocenteses at $200. I have assumed a 2-day course in the newborn intensive care unit for the infant at $1000 per day, one exchange transfusion at $400, and a slightly longer maternal stay at $200 per day (Table II). This patient was not severely enough sensitized to require an intrauterine transfusion, which would have added considerably to the cost. Even with these conservative assumptions the total comes to about $3600 per pregnancy. I wish to reemphasize that the most effective way to reduce the number of Rh-isoimmunized patients is to give Rh immune globulin to all candidates post partum. Since the majority of failures are due to sensitization before delivery, the second most effective method is to use antepartum Rh immune globulin. Although the number of patients sensitized because of an excess fetomaternal hemorrhage at the time of delivery is small, the cost of screening for this is also low, about one-fifth the cost of a dose

Table II. Cost of treatment for isoimmunized patient

Ultrasound and amniocentesis, 4 at $200	$ 800
Newborn intensive care unit, 2 days at $1000	$2000
Exchange transfusion at $400	$ 400
Additional maternal hospitalization, 2 days at $200	$ 400
Cost per sensitized patient	$3600

of Rh immune globulin. I therefore feel that consideration should be given to the routine use of a screening test such as the erythrocyte rosette test.

The authors have presented a strong case for the erythrocyte rosette test to screen for excess fetomaternal hemorrhage when Rh-negative women deliver Rh-positive infants. Before one can recommend the use of this test, however, I believe that a follow-up study should be performed to determine whether any patients using this method of screening became sensitized. I wish to ask the authors whether they have any information on the follow-up of these patients and whether they plan to evaluate systematically the effectiveness of their screening program.

Dr. Harry Farb, Minneapolis, Minnesota. Dr. Stedman and his colleagues have presented additional and encouraging information on the use of a rosette test as a more sensitive index of fetomaternal hemorrhage. In the past the available tests have included the tedious Kleihauer-Betke procedure and the relatively insensitive D^u test. The ultimate purpose is to detect excessive fetal hemorrhage into the maternal circulation at term in Rh-negative mothers and Rh-positive infants and, more recently, in the detection of fetomaternal hemorrhage in pregnant patients experiencing blunt abdominal trauma. Current Rh immune globulin prophylaxis of Rh sensitization is effective only if the fetomaternal hemorrhage is <30 ml of blood. If greater than that amount, the dose of Rh immune globulin must be increased to effectively suppress Rh sensitization. Some of this is accomplished at 28 weeks of gestation with the recently added dose of Rh immune globulin to the Rh-negative, unsensitized patient. However, even with 28-week therapy, occasional instances of excess fetomaternal hemorrhage occur, serving as a small risk of Rh sensitization.

The erythrocyte rosette test to detect fetomaternal hemorrhage is an interesting variation on D^u testing. The test is the same, the difference being that the ficin-treated Rh-positive red cells are a more sensitive index

of Rh-positive fetal cells than is antiglobulin serum. As a result, the erythrocyte rosette test will detect fetal Rh-positive red cells in maternal blood representing as little as a 2.5 ml fetomaternal hemorrhage.

A predicted result of switching from the D^u test to the erythrocyte rosette test is an increasing number of confirmatory Kleihauer-Betke tests for quantitation purposes. It also follows that more Rh immune globulin prophylaxis will be required. More philosophically and practically, the ideal test would be one that is limited to detecting only those fetomaternal hemorrhages of >30 ml of whole blood. Nevertheless, our laboratory plans to implement the erythrocyte rosette test as part of the RhoGAM workup within the next few weeks.

Of the 1000 consecutive Rh-negative patients who were delivered of Rh-positive infants in this study, 19 demonstrated a positive rosette test. Six of the 19 exceeded a 30 ml fetomaternal hemorrhage, and the only positive D^u test was in five of these six. No sample was positive by means of the D^u method when the fetomaternal hemorrhage was less than 30 ml, yet 16 of 40 artificial mixtures containing 2.5 ml to 20 ml fetal whole blood were positive by means of the D^u test. I would like to ask Dr. Stedman to comment on this finding.

Finally, I would like to point out that the D^u test failed to detect one fetomaternal hemorrhage of >30 ml among 1000 patients in this study. One might ask before replacing the D^u test with the rosette test. When is enough, enough? How completely effective does any therapeutic endeavor have to be? In addition, the American College of Obstetricians and Gynecologists has not recommended routine screening for excess fetomaternal hemorrhage, since the risk of sensitization is very low, even with hemorrhages >30 ml.[1] Would Dr. Stedman please comment on these concepts?

REFERENCE

1. American College of Obstetricians and Gynecologists. Prevention of Rho(D) isoimmunization. ACOG Technical Bulletin No. 79. Washington DC: ACOG, 1984.

Dr. Kenneth W. Crabb, St. Paul, Minnesota. First, concerning use of the rosette test at 28 weeks to determine which patients need antepartum prophylactic immunoglobulin, could we perhaps give a smaller dose, since the level of sensitivity is at 10 ml instead of 30 ml?

Second, can Dr. Stedman change the mechanical procedures of the test to change the sensitivity of the test?

Dr. Stedman (Closing). In regard to Dr. Kochenour's questions, the American College of Obstetricians and Gynecologists technical bulletin certainly conflicts with the published standards of the American Association of Blood Banks. I think it must be realized that most blood banks are now routinely screening for excessive fetomaternal hemorrhage, and we, as obstetricians, just do not know about it. If you query your local blood bank personnel, I think you will find that the majority of institutions are adhering to the standards of the American Association of Blood Banks, most commonly because it is the pathologist who determines the protocols.

The cost of screening, regardless of which test is being used, is also difficult to determine, since the blood bank usually has the charge hidden in the overall fee for Rh immunoglobulin. I think the figures that Dr. Kochenour used were very reasonable.

Concerning his question about a follow-up program, I think this is highly desirable, and we certainly hope a longitudinal study can be accomplished for those patients who did demonstrate an excessive fetomaternal hemorrhage. I might mention that one patient has demonstrated the presence of anti-D at 6 months post partum; assuming that sufficient Rh immune globulin was given after delivery, then in that particular patient one would have to theorize that the fetomaternal hemorrhage preceded delivery and anti-D was not yet detectable at the time Rh immune globulin was given.

In regard to Dr. Farb's question, I think I can best answer in this way: It is important to understand that the Kleihauer-Betke test as a gold standard is a little bit tarnished. It is just not as precise as we would like it to be. The 95% confidence interval for a value by the Kleihauer-Betke test is ±50%, and I think it is imperative to distinguish the theoretical 30 ml critical hemorrhage from the real-life situation. In fact, referring to the 1985 technical manual of the American Association of Blood Banks, administration of extra Rh immune globulin is advised even for a 20 ml hemorrhage (whole blood). Their rationale is that due to the confidence interval of the Kleihauer-Betke results, a 20 ml hemorrhage in reality might be a 30 ml hemorrhage. I think it is useful for everyone to review what is being done in their own institution.

We encountered two patients with estimated hemorrhages of 20 to 30 ml; one had a 24 ml hemorrhage and the other had a 28 ml hemorrhage. Since there were several hospitals participating in this study, we did not dictate how much Rh immune globulin was given, but both of those patients did receive two vials of Rh immune globulin.

Dr. Crabb asked a question about use of the rosette test at 28 weeks. The wonderful thing about the rosette test as a screening test is that it does not become positive for a hemorrhage that is a fraction of 1 ml; otherwise there would be so many false positives that additional technologists would be needed just to work up the positives. Therefore I think that use of the rosette test at 28 weeks would not really be helpul because sensitization can occur by exposure to <1 ml of fetal blood and the rosette test would be negative; so I really cannot endorse that application.

Dr. Crabb also asked whether the sensitivity of the test could be increased at all. I am not aware that this can be done. Again, it is solely a screening test. Currently we are performing an ongoing study evaluating the rosette test used in a quantitative fashion, and we will eventually compare the quantitative rosette test to a Kleihauer-Betke equivalent. This is for a future presentation.

vard Medical School, Department of Continuing Education, 25 Shattuck St., Boston, MA 02115.

Specialty Review in Obstetrics and Gynecology: Practical Aspects, September 15-20, 1986, Chicago, Illinois. For additional information, contact the Registrar's Office. Tel.: In Illinois 1 (800) 621-4649; outside Illinois 1 (800) 621-4651.

Current Trends in Reproductive Endocrinology, Infertility and Contraception, August 9-15, 1986, Waimea Beach Hotel, in Maui, Hawaii. For information contact: Beverly J. Johnson, Program Specialist, University of Southern California, Postgraduate Medical Education, 2025 Zonal Ave., Los Angeles, CA 90033. Tel.: (213) 224-7051.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Zwolska-Demczuk B (*see* Iffy et al). 1986; **154**:623-4

Subject index*

A

Abdominal hysterectomy
Are preoperative antibiotics helpful in abdominal hysterectomy? (Senior and Steigrad) 1986; **154**:1004-8
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6

ABO blood group
Maternal-fetal ABO/Rh antigenic relationships and human fetal development (Hoff and Bixler). 1986; **154**:126-9

Abortion
Analysis of the significance of discolored amniotic fluid detected at midtrimester amniocentesis (Zorn et al). 1986; **154**:1234-40
Caffeine consumption during pregnancy and association with late spontaneous abortion (Srisuphan and Bracken). 1986; **154**:14-20 •
Epidemiology of hydatidiform mole during early gestation (Atrash et al). 1986; **154**:906-9
Human chorionic gonadotropin in early normal and pathologic pregnancy (Steier et al). 1986; **154**:1091-4
Occurrence of molar pregnancy in patients undergoing elective abortion: Comparison with other clinical presentations (Ho Yuen and Callegari). 1986; **154**:273-6
The relationship between abortion in the first pregnancy and development of pregnancy-induced hypertension in the subsequent pregnancy (Strickland et al). 1986; **154**:146-8
Transfusions of leukocyte-rich erythrocyte concentrates: A successful treatment in selected cases of habitual abortion (Unander and Lindholm). 1986; **154**:516-20

Acetone
Effect of acetone precipitation on the clinical prediction of respiratory distress syndrome when utilizing amniotic fluid lecithin/sphingomyelin ratios (Hobson et al). 1986; **154**:1023-6

α_1-Acid glycoprotein
Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein (Mogensen et al) (Letter). 1986; **154**:1165-6

Acid-base status
Correlation of neonatal acid-base status with Apgar scores and fetal heart rate tracings (Page et al). 1986; **154**:1306-11
The relationship between antepartum fetal heart rate, intrapartum fetal heart rate, and fetal acid-base status (Low et al). 1986; **154**:769-76

Acoustic stimulation
Fetal response to vibratory acoustic stimulation in periods of low heart rate reactivity and low activity (Ohel et al). 1986; **154**:619-21

Actin
Pharmacologic levels of nitrendipine do not affect actin-myosin interaction in the human uterus and placenta (Sakamoto and Huszar). 1986; **154**:402-7

Adenocarcinoma; *see also* **Carcinoma**
Perforated adenocarcinoma of the appendix during pregnancy (Donnenfeld et al). 1986; **154**:637-8
Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study (Herbst et al). 1986; **154**:814-22

Adenosine
Maternal ovine placental vascular responses to adenosine (Landauer et al). 1986; **154**:1152-5

Adenosine monophosphate
Basal and forskolin-stimulated cyclic adenosine monophosphate in intact human platelets during the menstrual cycle (Pansini et al). 1986; **154**:679-82

Adhesions
A comparison of three techniques for ovarian reconstruction (Oelsner et al). 1986; **154**:569-72
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4

Adrenal tissue
Prostaglandin secretion by adrenal tissue of human anencephalic fetuses (Carr et al). 1986; **154**:373-8

β-Adrenergic agonist
Effect of hexoprenaline on uteroplacental blood flow in the pregnant rat (Lipshitz et al). 1986; **154**:310-4
Myometrial desensitization to continuous but not to intermittent β-adrenergic agonist infusion in the sheep (Casper and Lye). 1986; **154**:301-5

*January, 1-220; February, 221-476; March, 477-698; April, 699-972; May, 973-1172; June, 1173-1438.

α-Adrenergic receptor
α-Adrenergic receptors in human myometrium during pregnancy (Berg et al). 1986; **154**:601-6
Human platelet α-adrenergic receptors and responses during pregnancy: No change except that with differing hematocrit (Roberts et al). 1986; **154**:206-10

β-Adrenergic receptor
Effect of hexoprenaline on uteroplacental blood flow in the pregnant rat (Lipshitz et al). 1986; **154**:310-4
Failure to demostrate decreased β-adrenergic receptor concentration or decreased agonist efficacy in term or preterm human parturition (Dattel et al). 1986; **154**:450-6
Preterm labor: Its diagnosis and management (Gonik and Creasy). 1986; **154**:3-8 (Clin. Opinion)

Adrenocorticotropin
Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3

Age
Maternal and fetal surveillance for older pregnant women (Schipul Jr et al) (Letter); (Kirz) (Reply). 1986; **154**: 967-8
Ovarian cancer in the elderly: An analysis of surveillance, epidemiology, and end results program data (Yancik et al). 1986; **154**:639-47 (Curr. Dev.)

Air travel
Physiologic changes in pregnant women and their fetuses during jet air travel (Huch et al). 1986; **154**:996-1000

Alcohol
The effect of maternal consumption of alcohol on human umbilical artery blood flow (Erskine and Ritchie). 1986; **154**:318-21

Alloimmune thrombocytopenic purpura
Neonatal alloimmune thrombocytopenic purpura: A case report (Deaver et al). 1986; **154**:153-5

Ambulatory monitoring
Assessment of uterine activity in ambulatory patients at high risk of preterm labor and delivery (Katz et al). 1986; **154**:44-7

Amenorrhea
Plasma immunoreactive β-endorphin in exercise-associated amenorrhea (Laatikainen et al). 1986; **154**:94-7

American Gynecological and Obstetrical Society
Transactions of the fourth annual meeting of the American Gynecological and Obstetrical Society. 1986; **154**:699-854

American obstetric and gynecologic societies; *see also* **Papers; Transactions**
Roster of American obstetric and gynecologic societies. 1986; **154**:218-9

Aminophylline
Effect of aminophylline on lung maturation in preterm rabbit fetuses (Cosmi et al). 1986; **154**:436-9

Amniocentesis; *see also* **Amniotic fluid; Chorionic villus**
Amniostat-FLM: An initial clinical trial with both vaginal pool and amniocentesis samples (Benoit et al). 1986; **154**:65-8
Analysis of the significance of discolored amniotic fluid detected at midtrimester amniocentesis (Zorn et al). 1986; **154**:1234-40
Maternal serum α-fetoprotein and fetal autosomal trisomies (Doran et al). 1986; **154**:277-81

Amnion
Epithelial regulation of prolactin effect on amnionic permeability (Raabe and McCoshen). 1986; **154**:130-4

Amniotic fluid
Amniostat-FLM: An initial clinical trial with both vaginal pool and amniocentesis samples (Benoit et al). 1986; **154**:65-8
Amniotic fluid collagenase inhibitor: Correlation with gestational age and fetal lung maturity (Stricklin et al). 1986; **154**:134-9
Amniotic fluid ferning in early gestation (Borten and Friedman). 1986; **154**:628-30
Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity (Kogon et al). 1986; **154**:226-30
Analysis of the significance of discolored amniotic fluid detected at midtrimester amniocentesis (Zorn et al). 1986; **154**:1234-40
Effect of acetone precipitation on the clinical prediction of respiratory distress syndrome when utilizing amniotic fluid lecithin/sphingomyelin ratios (Hobson et al). 1986; **154**:1023-6
Elevated concentrations of the β-subunit of human chorionic gonadotropin and testosterone in the amniotic fluid of gestations of diabetic mothers (Barbieri et al). 1986; **154**:1039-43
Further studies on genital mycoplasmas in intra-amniotic infection: Blood cultures and serologic response (Gibbs et al). 1986; **154**:717-26
The in vivo effect of amniotic fluid on endocervical microflora (Patterson et al). 1986; **154**:1111-2
Interrelationship between amniotic fluid C-peptide and catecholamines in the last trimester of diabetic pregnancy (Pschera et al). 1986; **154**:48-52
Measurements of delta optical density at 450 nm in SS disease (Nelson) (Letter); (Lindsay and Lupo) (Reply). 1986; **154**:1166
A rapid method of culturing bloody amniotic fluid for chromosome analysis (Rodriguez et al) (Letter). 1986; **154**:969-70
Squamous cells in the maternal pulmonary circulation (Clark et al). 1986; **154**:104-6
Ultrasound evaluation of amniotic fluid: Outcome of pregnancies with severe oligohydramnios (Bastide et al). 1986; **154**:895-900
Use of the drop volume of amniotic fluic in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:63-74

Androgen
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Elevated concentrations of the β-subunit of human chorionic gonadotropin and testosterone in the amniotic fluid of gestations of diabetic mothers (Barbieri et al). 1986; **154**:1039-43
Testosterone levels and androgen-producing neoplasms (Meldrum) (Letter); (Friedman) (Reply). 1986;**154**:965-6
Treatment of severe androgen excess due to ovarian hyperthecosis with a long-acting gonadotropin-releasing hormone agonist (Steingold et al). 1986; **154**:1241-8

Anencephaly
Prostaglandin secretion by adrenal tissue of human anencephalic fetuses (Carr et al). 1986; **154**:373-8

Anesthesia
Oxygen consumption in fetal lambs after maternal administration of sodium pentobarbital (Rurak and Taylor). 1986; **154**:674-8

Angiotensin
Fetal responses to maternal infusions of angiotensin II (Perales et al). 1986; **154**:195-203
The relation of angiotensin-converting enzyme to the pregnancy-induced hypertension–preeclampsia syndrome (Goldkrand and Fuentes). 1986; **154**:792-800
Anomaly; *see also* specific anomaly
Antenatal diagnosis of renal anomalies with ultrasound. IV. Bilateral multicystic kidney disease (D'Alton et al). 1986; **154**:532-7
Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography (Copel et al). 1986; **154**:1121-32 (Curr. Dev.)
Endometriosis in association with uterine anomaly (Sanfilippo et al). 1986; **154**:39-43
Anterior pituitary; *see* **Pituitary**
Antiandrogenic therapy
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Antibiotics; *see also* specific agent
Are preoperative antibiotics helpful in abdominal hysterectomy? (Senior and Steigrad) 1986; **154**:1004-8
Antibody
An epidemic of maternal thrombocytopenia associated with elevated antiplatelet antibody (Hart et al). 1986; **154**:878-83
Kell sensitization in pregnancy (Caine and Mueller-Heubach). 1986; **154**:85-90
Mobiluncus-specific antibodies in a postoperative infection (Larsson et al) (Letter). 1986; **154**:1167-8
Transfusions of leukocyte-rich erythrocyte concentrates: A successful treatment in selected cases of habitual abortion (Unander and Lindholm). 1986; **154**:516-20
Anticoagulant
Lupus anticoagulant and pregnancy (Spitz et al) (Letter). 1986; **154**:1169
Antigen
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
Maternal-fetal ABO/Rh antigenic relationships and human fetal development (Hoff and Bixler). 1986; **154**:126-9
Neonatal alloimmune thrombocytopenic purpura: A case report (Deaver et al). 1986; **154**:153-5
Prevalence of hepatitis B surface antigen among women receiving prenatal care at the Palm Beach County Health Department (Malecki et al). 1986; **154**:625-6
Anti-Kell antibody
Kell sensitization in pregnancy (Caine and Mueller-Heubach). 1986; **154**:85-90
Antiplatelet antibody
An epidemic of maternal thrombocytopenia associated with elevated antiplatelet antibody (Hart et al). 1986; **154**:878-83
Anxiety
Postpartum moods in men and women (Quadagno et al). 1986; **154**:1018-23
Aorta
Aortic function during normal human pregnancy (Hart et al). 1986; **154**:887-91
Apgar score
Correlation of neonatal acid-base status with Apgar scores and fetal heart rate tracings (Page et al). 1986; **154**:1306-11
Appendix
Perforated adenocarcinoma of the appendix during pregnancy (Donnenfeld et al). 1986; **154**:637-8
Arginine
Blunted response of maternal ovine placental lactogen levels to arginine stimulation after single umbilical artery ligation in pregnant sheep (Newnham et al). 1986; **154**:663-6
Sodium excretion in human pregnancy: A role for arginine vasopressin (Brown and Gallery). 1986; **154**:914-9
Asphyxia
Birth asphyxia, trauma, and mortality in twins: Has cesarean section improved outcome? (Bell et al). 1986; **154**:235-9
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
Autoimmune disease
Breast-feeding in thrombocytopenic neonates secondary to maternal autoimmune thrombocytopenic purpura (Meschengieser and Lazzari) (Letter); (Martin Jr) (Reply). 1986; **154**:1166-7
Transfusions of leukocyte-rich erythrocyte concentrates: A successful treatment in selected cases of habitual abortion (Unander and Lindholm). 1986; **154**:516-20
Autosomal trisomy
Maternal serum α-fetoprotein and fetal autosomal trisomies (Doran et al). 1986; **154**:277-81

B

Bacteria; *see also* **Flora; Infection**
Bacterial flora of the cervix in women using different methods of contraception (Haukkamaa et al). 1986; **154**:520-4
Etiology of cervical inflammation (Paavonen et al). 1986; **154**:556-64
Barbiturates
Oxygen consumption in fetal lambs after maternal administration of sodium pentobarbital (Rurak and Taylor). 1986; **154**:674-8
Behavior
The effect of electrical stimulation on behavioral states in the fetal lamb (Natale and Nasello-Paterson). 1986; **154**:321-8
Biofeedback
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64
Biophysical profile scoring
Biophysical profile scoring in the management of the postterm pregnancy: An analysis of 307 patients (Johnson et al). 1986; **154**:269-73
Biopsy
Human papillomavirus infection of the cervix detected by cervicovaginal lavage and molecular hybridization: Correlation with biopsy results and Papanicolaou smear (Burk et al). 1986; **154**:982-9
Necessity of endocervical curettage in colposcopy (Moseley et al). 1986; **154**:992-5
Birth; *see* **Delivery**
Birth injury
Fetal injury prior to labor: Does it happen? (Paul et al) 1986; **154**:1187-93
Perinatal events and cerebral palsy (Hensleigh et al). 1986; **154**:978-81

Birth weight
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Prepregnancy weight, weight gain, and birth weight (Abrams and Laros Jr). 1986; **154**:503-9
Bladder sphincter
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64
Bleeding; *see* **Hemorrhage**
Is there a causal connection between motile curved rods, *Mobiluncus* species, and bleeding complications? (Larsson and Bergman). 1986; **154**:107-8
Blood group
Maternal-fetal ABO/Rh antigenic relationships and human fetal development (Hoff and Bixler). 1986; **154**:126-9
Blood sampling
Percutaneous umbilical sampling in immune thrombocytopenic purpura (Sacks) (Letter); (Hobbins et al) (Reply). 1986; **154**:214-5
Blood transfusion
Blood transfusions and Jehovah's Witnesses: Medical and legal issues in obstetrics and gynecology (Sacks and Koppes). 1986; **154**:483-6 (Clin. Opinion)
Blood volume expansion
Cardiovascular alterations in severe pregnancy-induced hypertension: Effects of intravenous nitroglycerin coupled with blood volume expansion (Cotton et al). 1986; **154**:1053-9
Books received
Books received. 1986; **154**:696, 971, 1171, 1370
Bowel obstruction
Disagreement on use of water-soluble contrast material in small bowel obstruction (Ott et al) (Letter); (Robertson) (Reply). 1986; **154**:690-1
Postoperative intussusception after vaginal vault suspension (Hunter et al). 1986; **154**:633-4
Breast
Fibrocystic breast disease: Pathophysiology, pathomorphology, clinical picture, and management (Vorherr). 1986; **154**:161-79
Lactation suppression and puerperal fever (Almeida and Kitay). 1986; **154**:940-1
On the origin and progression of human breast cancer (Jensen). 1986; **154**:1280-4
Breast-feeding
Breast-feeding in thrombocytopenic neonates secondary to maternal autoimmune thrombocytopenic purpura (Meschengieser and Lazzari) (Letter); (Martin Jr) (Reply). 1986; **154**:1166-7
Excretion of varicella–herpes zoster virus in breast milk (Frederick et al). 1986; **154**:1116-7
Influence of breast-feeding on the restoration of the low serum concentration of vitamin E and β-carotene in the newborn infant (Ostrea Jr et al). 1986; **154**:1014-7
Breech presentation
Abdominal rescue after entrapment of the aftercoming head (Iffy et al). 1986; **154**:623-4
External cephalic version of the breech presentation under tocolysis (Morrison et al). 1986; **154**:900-3
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
The length of the human umbilical cord in vertex and breech presentations (Soernes and Bakke). 1986; **154**:1086-7
Bromocriptine
Inhibition of human chorionic gonadotropin production by prolactin from term human trophoblast (Ho Yuen et al). 1986; **154**:336-40
Lactation suppression and puerperal fever (Almeida and Kitay). 1986; **154**:940-1
Pergolide and bromocriptine for the treatment of patients with hyperprolactinemia (Kletzky et al). 1986; **154**:431-5

C

CA 125
CA 125 surveillance and second-look laparotomy in ovarian carcinoma (Atack et al). 1986; **154**:287-9
The tumor marker CA 125 is a common constituent of normal cervical mucus (de Bruijn et al). 1986; **154**:1088-91
Caffeine
Caffeine consumption during pregnancy and association with late spontaneous abortion (Srisuphan and Bracken). 1986; **154**:14-20
Calcium channel blocker
The effect of a calcium channel blocker (nifedipine) on uterine blood flow in the pregnant goat (Veille et al). 1986; **154**:1160-3
Pharmacologic levels of nitrendipine do not affect actin-myosin interaction in the human uterus and placenta (Sakamoto and Huszar). 1986; **154**:402-7
Cannulas
A randomized study of three cannulas for transcervical chorionic villus sampling (MacKenzie et al). 1986; **154**:34-9
Carbon dioxide laser
Toxic shock syndrome following carbon dioxide laser treatment of genital tract condyloma acuminatum (Bowen et al). 1986; **154**:145-6
Carcinoma; *see also* **Neoplasia**
CA 125 surveillance and second-look laparotomy in ovarian carcinoma (Atack et al). 1986; **154**:287-9
Cervical carcinoma in women aged 34 and younger (Carmichael et al). 1986; **154**:264-9
Cigarette smoking and endometrial cancer (Baron) (Letter). 1986; **154**:965
The effect of dehydroepiandrosterone sulfate on de novo and low-density lipoprotein–stimulated progesterone secretion by human choriocarcinoma JEG-3 cells (Moise et al). 1986; **154**:1080-5
Human papillomavirus deoxyribonucleic acid in cervical carcinoma from primary and metastatic sites (Lancaster et al). 1986; **154**:115-9
On the origin and progression of human breast cancer (Jensen). 1986; **154**:1280-4
Ovarian cancer in the elderly: An analysis of surveillance, epidemiology, and end results program data (Yancik et al). 1986; **154**:639-47 (Curr. Dev.)
Ovarian carcinoma of low malignant potential: Staging and treatment (Nation and Krepart). 1986; **154**:290-3
Perforated adenocarcinoma of the appendix during pregnancy (Donnenfeld et al). 1986; **154**:637-8
Primary carcinoma of the fallopian tube (Podratz et al). 1986; **154**:1319-26
Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study (Herbst et al). 1986; **154**:814-22
The role of lymphangiography in vulvar carcinoma (Weiner et al). 1986; **154**:1073-5
Staging laparotomy in early epithelial ovarian carcinoma (Helewa et al). 1986; **154**:282-6

Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6
Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein (Mogensen et al) (Letter). 1986; **154**:1165-6

Cardiovascular disease; *see* Heart

β-Carotene
Influence of breast-feeding on the restoration of the low serum concentration of vitamin E and β-carotene in the newborn infant (Ostrea Jr et al). 1986; **154**:1014-7

Case reports
The value of case reports in human teratology (Goldberg and Golbus). 1986; **154**:479-82 (Clin. Opinion)

Catecholamine
Interrelationship between amniotic fluid C-peptide and catecholamines in the last trimester of diabetic pregnancy (Pschera et al). 1986; **154**:48-52
Plasma catecholamine responses to physiologic stimuli in normal human pregnancy (Barron et al). 1986; **154**: 80-4

Cefotetan
Cefotetan in the treatment of obstetric and gynecologic infections (Poindexter III et al). 1986; **154**:946-50 (Symposium)
Cefotetan versus cefoxitin as prophylaxis in hysterectomy (Orr Jr et al). 1986; **154**:960-3 (Symposium)
Comparison of cefotetan and cefoxitin as prophylaxis in cesarean section (Varner et al). 1986; **154**:951-4 (Symposium)
Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients (McGregor et al). 1986; **154**:955-60 (Symposium)
Symposium on Cefotetan: Introduction (Quintiliani). 1986; **154**:945 (Symposium)

Cefoxitin
Are preoperative antibiotics helpful in abdominal hysterectomy? (Senior and Steigrad) 1986; **154**:1004-8
Cefotetan versus cefoxitin as prophylaxis in hysterectomy (Orr Jr et al). 1986; **154**:960-3 (Symposium)
Comparison of cefotetan and cefoxitin as prophylaxis in cesarean section (Varner et al). 1986; **154**:951-4 (Symposium)
Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients (McGregor et al). 1986; **154**:955-60 (Symposium)

Central Association of Obstetricians and Gynecologists
Transactions of the fifty-third annual meeting of the Central Association of Obstetricians and Gynecologists. 1986; **154**:1285-1369

Cephalic version
External cephalic version of the breech presentation under tocolysis (Morrison et al). 1986; **154**:900-3

Cephalopelvic disproportion
Factors related to the increasing cesarean section rates for cephalopelvic disproportion (Silbar). 1986; **154**: 1095-8

Cephradine
Are preoperative antibiotics helpful in abdominal hysterectomy? (Senior and Steigrad) 1986; **154**:1004-8

Cerebral palsy
Perinatal events and cerebral palsy (Hensleigh et al). 1986; **154**:978-81

Cervical factor
Experience with intrauterine insemination for cervical factor and oligospermia (Hull et al). 1986; **154**:1333-8

Cervix
An analysis of the factors involved in the colposcopic evaluation of 2194 patients with abnormal Papanicolaou smears (Wetrich). 1986; **154**:1339-49
Bacterial flora of the cervix in women using different methods of contraception (Haukkamaa et al). 1986; **154**: 520-4
Cervical carcinoma in women aged 34 and younger (Carmichael et al). 1986; **154**:264-9
Cervical intraepithelial neoplasia and condyloma: An analysis of diagnostic accuracy of posttreatment follow-up methods (Falcone and Ferenczy). 1986; **154**:260-4
Etiology of cervical inflammation (Paavonen et al). 1986; **154**:556-64
Human papillomavirus deoxyribonucleic acid in cervical carcinoma from primary and metastatic sites (Lancaster et al). 1986; **154**:115-9
Human papillomavirus infection of the cervix detected by cervicovaginal lavage and molecular hybridization: Correlation with biopsy results and Papanicolaou smear (Burk et al). 1986; **154**:982-9
The in vivo effect of amniotic fluid on endocervical microflora (Patterson et al). 1986; **154**:1111-2
Necessity of endocervical curettage in colposcopy (Moseley et al). 1986; **154**:992-5
Preinduction cervical ripening with sequential use of prostaglandin E_2 gel (Prins et al). 1986; **154**:1275-9
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6
Treatment of cervical intraepithelial neoplasia with electrocautery: A report of 776 cases (Deigen et al). 1986; **154**:255-9
The tumor marker CA 125 is a common constituent of normal cervical mucus (de Bruijn et al). 1986; **154**:1088-91
Ultrasound differentiation of the competent from the incompetent cervix: Prevention of preterm delivery (Michaels et al). 1986; **154**:537-46

Cesarean section
Abdominal rescue after entrapment of the aftercoming head (Iffy et al). 1986; **154**:623-4
Birth asphyxia, trauma, and mortality in twins: Has cesarean section improved outcome? (Bell et al). 1986; **154**: 235-9
Cesarean delivery of the second twin after vaginal delivery of the first twin (Rattan et al). 1986; **154**:936-9
Comparison of cefotetan and cefoxitin as prophylaxis in cesarean section (Varner et al). 1986; **154**:951-4 (Symposium)
Factors related to the increasing cesarean section rates for cephalopelvic disproportion (Silbar). 1986; **154**: 1095-8
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients (McGregor et al). 1986; **154**:955-60 (Symposium)
Single-dose trimethoprim-sulfamethoxazole prophylaxis for cesarean section (Ganesh et al). 1986; **154**:1113-4

Change
Change and consistency (Brewer et al). 1986; **154**:1-2 (Editorial)

Chemotherapy
Ovarian carcinoma of low malignant potential: Staging and treatment (Nation and Krepart). 1986; **154**:290-3
Chlamydia trachomatis
Etiology of cervical inflammation (Paavonen et al). 1986; **154**:556-64
Localization of *Chlamydia trachomatis* infection by direct immunofluorescence and culture in pelvic inflammatory disease (Kiviat et al). 1986; **154**:865-73
Residues of pelvic inflammatory disease in intrauterine device users: A result of the intrauterine device or *Chlamydia trachomatis* infection? (Guderian and Trobough). 1986; **154**:497-503
Choriocarcinoma
Demonstration of myc and ras oncogene expression by hybridization in situ in hydatidiform mole and in the BeWo choriocarcinoma cell line (Sarkar et al). 1986; **154**:390-3
The effect of dehydroepiandrosterone sulfate on de novo and low-density lipoprotein–stimulated progesterone secretion by human choriocarcinoma JEG-3 cells (Moise et al). 1986; **154**:1080-5
Chorionic gonadotropin; *see* **Gonadotropin**
Chorionic villus; *see also* **Amniocentesis**
Chorionic villus sampling: Experience of the first 1000 cases (Hogge et al). 1986; **154**:1249-52
Chorionic villus sampling in continuing pregnancies. I. Low fetal loss rates in initial 109 cases (Elias et al). 1986; **154**:1349-52
Chorionic villus sampling in continuing pregnancies. II. Cytogenetic reliability (Martin et al). 1986; **154**:1353-62
Improving the yield of direct chorionic villus slide preparations (Bhatia et al). 1986; **154**:408-11
A randomized study of three cannulas for transcervical chorionic villus sampling (MacKenzie et al). 1986; **154**:34-9
Septic shock with renal failure after chorionic villus sampling (Barela et al). 1986; **154**:1100-2
Chromosome
Hydrops fetalis and chromosomal trisomies (Landrum et al). 1986; **154**:1114-5
A rapid method of culturing bloody amniotic fluid for chromosome analysis (Rodriguez et al) (Letter). 1986; **154**:969-70
Use of two different deoxyribonucleic acid probes to detect Y chromosome deoxyribonucleic acid in subjects with normal and altered Y chromosomes (McDonough et al). 1986; **154**:737-48
Cigarette smoking
Cigarette smoking and endometrial cancer (Baron) (Letter). 1986; **154**:965
Circulation
Circulatory responses to hypovolemia in the pregnant and nonpregnant sheep after pharmacologic sympathectomy (Tabsh et al). 1986; **154**:411-9
Clear cell adenocarcinoma
Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study (Herbst et al). 1986; **154**:814-22
Clinical Opinion
Clinical Opinion. 1986; **154**:3-13, 479-86, 973-81
Clomiphene citrate
The effects of enclomiphene and zuclomiphene citrates on mouse embryos fertilized in vitro and in vivo (Schmidt et al). 1986; **154**:727-36
Colectomy
Perforated adenocarcinoma of the appendix during pregnancy (Donnenfeld et al). 1986; **154**:637-8
Collagenase inhibitor
Amniotic fluid collagenase inhibitor: Correlation with gestational age and fetal lung maturity (Stricklin et al). 1986; **154**:134-9
Colonization; *see* **Flora**
Microbial colonization of tailed and tailless intrauterine contraceptive devices: Influence of the mode of insertion in the rabbit (Jacques et al). 1986; **154**:648-55
Colpocleisis
Partial colpocleisis (Langmade and Oliver Jr). 1986; **154**:1200-5
Colposcopy
An analysis of the factors involved in the colposcopic evaluation of 2194 patients with abnormal Papanicolaou smears (Wetrich). 1986; **154**:1339-49
Behavior of the squamocolumnar junction during normal pregnancy (Ganesh et al) (Letter). 1986; **154**:689-90
Cervical intraepithelial neoplasia and condyloma: An analysis of diagnostic accuracy of posttreatment follow-up methods (Falcone and Ferenczy). 1986; **154**:260-4
Colposcopy in the diagnosis of penile condyloma (Sedlacek et al). 1986; **154**:494-6
Necessity of endocervical curettage in colposcopy (Moseley et al). 1986; **154**:992-5
Treatment of cervical intraepithelial neoplasia with electrocautery: A report of 776 cases (Deigen et al). 1986; **154**:255-9
Condyloma
Cervical intraepithelial neoplasia and condyloma: An analysis of diagnostic accuracy of posttreatment follow-up methods (Falcone and Ferenczy). 1986; **154**:260-4
Colposcopy in the diagnosis of penile condyloma (Sedlacek et al). 1986; **154**:494-6
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Toxic shock syndrome following carbon dioxide laser treatment of genital tract condyloma acuminatum (Bowen et al). 1986; **154**:145-6
Congenital anomaly; *see also* **specific anomaly**
Antenatal diagnosis of renal anomalies with ultrasound. IV. Bilateral multicystic kidney disease (D'Alton et al). 1986; **154**:532-7
Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography (Copel et al). 1986; **154**:1121-32 (Curr. Dev.)
Conization
Additional comment on combination conization (Townsend). 1986; **154**:967
Necessity of endocervical curettage in colposcopy (Moseley et al). 1986; **154**:992-5
Conjugated equine estrogen
Biochemical and histologic effects of sequential estrogen/progestin therapy on the endometrium of postmenopausal women (Gibbons et al). 1986; **154**:456-61
Consistency
Change and consistency (Brewer et al). 1986; **154**:1-2 (Editorial)
Constrictive pericarditis
Constrictive pericarditis and pregnancy (Sachs et al). 1986; **154**:156-7
Contraception; *see also* **Intrauterine device**
Bacterial flora of the cervix in women using different methods of contraception (Haukkamaa et al). 1986; **154**:520-4

Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Toxic shock syndrome, contraceptive methods, and vaginitis (Lanes et al). 1986; **154**:989-91

Contrast material
Disagreement on use of water-soluble contrast material in small bowel obstruction (Ott et al) (Letter); (Robertson) (Reply). 1986; **154**:690-1

Coronary artery disease
Coronary artery disease in diabetic pregnancies (Reece et al). 1986; **154**:150-1
Estrogen use and cardiovascular disease (Henderson et al). 1986; **154**:1181-6

Corpus luteum
Human ovarian oxytocin: Its source and relationship to steroid hormones (Dawood and Khan-Dawood). 1986; **154**:756-63
Ovarian pregnancy with a contralateral corpus luteum: Case report (Check and Chase). 1986; **154**:155-6

Correspondence
Letters. 1986; **154**:211-7, 689-95, 964-70, 1164-70

Corticotropin
Corticotropin-releasing factor can stimulate gonadotropin secretion by human fetal pituitaries in superfusion (Blumenfeld et al). 1986; **154**:606-12

Cortisol
Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3

C-peptide
Interrelationship between amniotic fluid C-peptide and catecholamines in the last trimester of diabetic pregnancy (Pschera et al). 1986, **154**:48-52

C-reactive protein
Serum C-reactive protein determination in acute pelvic inflammatory disease (Lehtinen et al). 1986; **154**:158-9

Cultures
An evaluation of different media for the zona-free hamster egg penetration test (Mortimer). 1986; **154**:351-4
Further studies on genital mycoplasms in intra-amniotic infection: Blood cultures and serologic response (Gibbs et al). 1986; **154**:717-26
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
A rapid method of culturing bloody amniotic fluid for chromosome analysis (Rodriguez et al) (Letter). 1986 **154**:969-70

Curettage
Necessity of endocervical curettage in colposcopy (Moseley et al). 1986; **154**:992-5

Current development
Current development. 1986; **154**:639-47, 1121-32

Cushing's syndrome
Cushing's syndrome in pregnancy: A case report and literature review (Koerten et al). 1986; **154**:626-8

Cyclic adenosine monophosphate
Basal and forskolin-stimulated cyclic adenosine monophosphate in intact human platelets during the menstrual cycle (Pansini et al). 1986; **154**:579-82

Cyproterone acetate
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44

Cystic hygroma colli
Fetal cystic hygroma colli: Antenatal diagnosis, significance, and management (Garden et al). 1986; **154**:221-5

Cystourethropexy
Modified retropubic cystourethropexy (Goodno Jr and Powers). 1986; **154**:1211-5

D

Danazol
Inhibition of gonadotropin-releasing hormone receptors in rat anterior pituitary monolayer cell cultures by danazol (Menon et al). 1986; **154**:362-72
Relationship of gonadotropin-releasing hormone, danazol, and prostaglandin blockade to ovarian enlargement and ascites formation of the ovarian hyperstimulation syndrome in the rabbit (Pride et al). 1986; **154**:1155-60

Death; *see* Mortality

Dehydroepiandrosterone sulfate
The effect of dehydroepiandrosterone sulfate on de novo and low-density lipoprotein–stimulated progesterone secretion by human choriocarcinoma JEG-3 cells (Moise et al). 1986; **154**:1080-5

Delivery
Abdominal rescue after entrapment of the aftercoming head (Iffy et al). 1986; **154**:623-4
Birth asphyxia, trauma, and mortality in twins: Has cesarean section improved outcome? (Bell et al). 1986; **154**:235-9
Cesarean delivery of the second twin after vaginal delivery of the first twin (Rattan et al). 1986; **154**:936-9
Failure to demostrate decreased β-adrenergic receptor concentration or decreased agonist efficacy in term or preterm human parturition (Dattel et al). 1986; **154**:450-6
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
Midforceps deliveries: Long-term outcome of infants (Dierker Jr et al). 1986; **154**:764-8
Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3
Reply to Dr. Emanuel Friedman (Kadar) (Letter). 1986; **154**:694-5
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9

Deoxyribonucleic acid
Human papillomavirus deoxyribonucleic acid in cervical carcinoma from primary and metastatic sites (Lancaster et al). 1986; **154**:115-9
Use of two different deoxyribonucleic acid probes to detect Y chromosome deoxyribonucleic acid in subjects with normal and altered Y chromosomes (McDonough et al). 1986; **154**:737-48

Desensitization
Myometrial desensitization to continuous but not to intermittent β-adrenergic agonist infusion in the sheep (Casper and Lye). 1986; **154**:301-5

Development
The influence of prolonged pregnancy on infant development at one and two years of age: A prospective controlled study (Shime et al). 1986; **154**:341-5

Dexamethasone
The effect of antenatal dexamethasone on maternal and fetal retinol-binding protein (Hustead and Zachman). 1986; **154**:203-5
The effect of antenatal dexamethasone administration on the prevention of respiratory distress syndrome in preterm gestations with premature rupture of membranes (Morales et al). 1986; **154**:591-5
Diabetes
Coronary artery disease in diabetic pregnancies (Reece et al). 1986; **154**:150-1
The current role of daily serum estriol monitoring in the insulin-dependent pregnant diabetic woman (Ray et al). 1986; **154**:1257-63
Decreased fetal cord prolactin concentration in diabetic pregnancies (Saltzman et al). 1986; **154**:1035-8
Elevated concentrations of the β-subunit of human chorionic gonadotropin and testosterone in the amniotic fluid of gestations of diabetic mothers (Barbieri et al). 1986; **154**:1039-43
Fetal α-melanocyte–stimulating homone levels: No correlation with late fetal growth but increased with diabetes mellitus (Hassan et al). 1986; **154**:428-30
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Glucose threshold for macrosomia in pregnancy complicated by diabetes (Willman et al). 1986; **154**:470-5
Interrelationship between amniotic fluid C-peptide and catecholamines in the last trimester of diabetic pregnancy (Pschera et al). 1986; **154**:48-52
Serum fructosamine: A screening test for diabetes in pregnancy (Roberts and Baker). 1986; **154**:1027-30
Should a fifty-gram, one-hour plasma glucose screening test for gestational diabetes be administered in the fasting or fed state? (Coustan et al) 1986; **154**:1031-5
Diagnosis related groups
Obstetric hospital stays by diagnosis related groups: A community-based analysis (Lagoe). 1986; **154**:873-8
Diet
Effect of long-term administration of β_2-sympathomimetic drug in the diet-restricted pregnant rat model (Lipshitz et al). 1986; **154**:314-7
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Diethylstilbestrol
Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study (Herbst et al). 1986; **154**:814-22
Treatment of endometriosis (Lockhart Jr) (Letter). 1986; **154**:215-6
Upper genital tract changes and infertility in diethylstilbestrol-exposed women (Kaufman et al). 1986; **154**:1312-8
Dopamine
Circulatory responses to hypovolemia in the pregnant and nonpregnant sheep after pharmacologic sympathectomy (Tabsh et al). 1986; **154**:411-9
Modulation of luteinizing hormone immunoreactivity and bioactivity by dopamine but not norepinephrine in women (Barnes et al). 1986; **154**:445-50
Pergolide and bromocriptine for the treatment of patients with hyperprolactinemia (Kletzky et al). 1986; **154**:431-5
Variability and selectivity of anterior pituitary response to dopamine agonists throughout the normal menstrual cycle (Kletzky and Shangold). 1986; **154**:362-7
Doppler measurement
Failure of nonstress test and Doppler-assessed umbilical arterial blood flow to detect imminent intrauterine death (Erskine et al). 1986; **154**:1109-10
Quantitative two-dimensional echocardiographic assessment of fetal cardiac growth (Shime et al). 1986; **154**:294-300
Uterine artery Doppler velocimetry in pregnant women with hypertension (Fleischer et al). 1986; **154**:806-13
Down's syndrome
A sonographic sign for fetal Down's syndrome (Defoort and Thiery) (Letter). 1986; **154**:1169-70
Drop volume
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74
Dysmaturity
The influence of prolonged pregnancy on infant development at one and two years of age: A prospective controlled study (Shime et al). 1986; **154**:341-5
Dyspareunia
Focal vulvitis: A characteristic syndrome and cause of dyspareunia: Features, natural history, and management (Peckham et al). 1986; **154**:855-64
Dystocia
Another technique for resolution of shoulder dystocia (Carter) (Letter). 1986; **154**:964

E

Echocardiography
Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography (Copel et al). 1986; **154**:1121-32 (Curr. Dev.)
Quantitative two-dimensional echocardiographic assessment of fetal cardiac growth (Shime et al). 1986; **154**:294-300
Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women (Sánchez et al). 1986; **154**:910-3
Eclampsia; *see also* **Preeclampsia**
Eclampsia. V. The incidence of nonpreventable eclampsia (Sibai et al). 1986; **154**:581-90
Hypertensive diseases of pregnancy and parity (Gleicher et al). 1986; **154**:1044-9
Ectopic pregnancy
Conservative treatment of ectopic pregnancy with methotrexate (Ory et al). 1986; **154**:1299-1306
Tubal conservation in ectopic pregnancy: A study of 200 cases (Hallatt). 1986; **154**:1216-21
Edema
Leg static pressure values in pregnant women with iatrogenic pulmonary edema (Goodlin). 1986; **154**:634-5
Role of intravenous nitroglycerin in the treatment of severe pregnancy-induced hypertension complicated by pulmonary edema (Cotton et al). 1986; **154**:91-3
Editorials
Editorial. 1986; **154**:1-2, 477-8
Education; *see also* **Residency**
The Golden Thread (Malkasian Jr). 1986; **154**:1285-90 (Pres. address)
The need for flexibility in preparing clinician-scientists for academic careers (Jaffe). 1986; **154**:778-80 (Symposium)

Egg penetration test
An evaluation of different media for the zona-free hamster egg penetration test (Mortimer). 1986; **154**:551-4
Elderly; *see* **Age**
Electrical stimulation
The effect of electrical stimulation on behavioral states in the fetal lamb (Natale and Nasello-Paterson). 1986; **154**:321-8
Electrocardiogram
Electrocardiographic changes associated with ritodrine-induced maternal tachycardia and hypokalemia (Hendricks et al). 1986; **154**:921-3
Electrocautery
Treatment of cervical intraepithelial neoplasia with electrocautery: A report of 776 cases (Deigen et al). 1986; **154**:255-9
Embryo; *see also* **Embryo transfer**
The effects of enclomiphene and zuclomiphene citrates on mouse embryos fertilized in vitro and in vivo (Schmidt et al). 1986; **154**:727-36
Embryo transfer; *see also* **Fertilization**
An obstetric assessment of the first 100 births from the in vitro fertilization program at Clamart, France (Frydman et al). 1986; **154**:550-5
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4
An in vitro fertilization and embryo transfer pilot study: Treatment-dependent and treatment-independent pregnancies (Jarrell et al). 1986; **154**:231-4
Emphysema
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9
Encephalitis
Meningoencephalitis caused by *Histoplasma capsulatum* complicating pregnancy (McGregor et al). 1986; **154**:925-31
Enclomiphene citrate
The effects of enclomiphene and zuclomiphene citrates on mouse embryos fertilized in vitro and in vivo (Schmidt et al). 1986; **154**:727-36
Endocarditis
Infective endocarditis in obstetric and gynecologic practice (Seaworth and Durack). 1986; **154**:180-8
Endocervix; *see also* **Cervix**
The in vivo effect of amniotic fluid on endocervical microflora (Patterson et al). 1986; **154**:1111-2
Necessity of endocervical curettage in colposcopy (Moseley et al). 1986; **154**:992-5
Endometriosis
Analysis of sequential treatment protocols for endometriosis-associated infertility (Olive and Lee). 1986; **154**:613-9
Endometriosis in association with uterine anomaly (Sanfilippo et al). 1986; **154**:39-43
Family trait analysis: A case-control study of 43 women with endometriosis and their best friends (Lamb et al). 1986; **154**:596-601
Peritoneal fluid in patients with and without endometriosis: Prostanoids and macrophages and their effect on the spermatozoa penetration assay (Chacho et al). 1986; **154**:1290-9
Prostaglandins and endometriosis (Sgarlata and Hertelendy) (Letter); (James) (Reply). 1986; **154**:964-5
Treatment of endometriosis (Lockhart Jr) (Letter). 1986; **154**:215-6
Endometritis
Cefotetan in the treatment of obstetric and gynecologic infections (Poindexter III et al). 1986; **154**:946-50 (Symposium)
Serum C-reactive protein determination in acute pelvic inflammatory disease (Lehtinen et al). 1986; **154**:158-9
Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients (McGregor et al). 1986; **154**:955-60 (Symposium)
Single-dose trimethoprim-sulfamethoxazole prophylaxis for cesarean section (Ganesh et al). 1986; **154**:1113-4
Endometrium; *see also* **Endometriosis; Endometritis**
Basal and forskolin-stimulated cyclic adenosine monophosphate in intact human platelets during the menstrual cycle (Pansini et al). 1986; **154**:679-82
Biochemical and histologic effects of sequential estrogen/progestin therapy on the endometrium of postmenopausal women (Gibbons et al). 1986; **154**:456-61
Cigarette smoking and endometrial cancer (Baron) (Letter). 1986; **154**:965
β-Endorphin
Plasma immunoreactive β-endorphin in exercise-associated amenorrhea (Laatikainen et al). 1986; **154**:94-7
Engorgement
Lactation suppression and puerperal fever (Almeida and Kitay). 1986; **154**:940-1
Entrapment of aftercoming head
Abdominal rescue after entrapment of the aftercoming head (Iffy et al). 1986; **154**:623-4
Enzyme-linked immunosorbent assay
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
Epinephrine
Plasma catecholamine responses to physiologic stimuli in normal human pregnancy (Barron et al). 1986; **154**:80-4
Epithelium
Epithelial regulation of prolactin effect on amnionic permeability (Raabe and McCoshen). 1986; **154**:130-4
Errata
Alloimmunization in twin pregnancies (Bowman) (1985; **153**:10-1). 1986; **154**:217
Heat flux and oxygen consumption of the pregnant uterus (1986; **154**:462-9). 1986; **154**:695
Erythroblastosis fetalis; *see* **Rh isoimmunization**
Erythrocyte
The effects of fetal exchange transfusion with a red blood cell substitute (Ambrose et al). 1986; **154**:667-74
Transfusions of leukocyte-rich erythrocyte concentrates: A successful treatment in selected cases of habitual abortion (Unander and Lindholm). 1986; **154**:516-20
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9
Erythromycin
Adjunctive erythomycin treatment for idiopathic preterm labor: Results of a randomized, double-blinded, placebo-controlled trial (McGregor et al). 1986; **154**:98-103
Escherichia coli
Vaginal colonization with *Escherichia coli* in healthy women (Chow et al). 1986; **154**:120-6
Estriol
The current role of daily serum estriol monitoring in the insulin-dependent pregnant diabetic woman (Ray et al). 1986; **154**:1257-63

Estrogen
Biochemical and histologic effects of sequential estrogen/progestin therapy on the endometrium of postmenopausal women (Gibbons et al). 1986; **154**:456-61
Estrogen use and cardiovascular disease (Henderson et al). 1986; **154**:1181-6
Fibrocystic breast disease: Pathophysiology, pathomorphology, clinical picture, and management (Vorherr). 1986; **154**:161-79
Human ovarian oxytocin: Its source and relationship to steroid hormones (Dawood and Khan-Dawood). 1986; **154**:756-63
Temporal and receptor correlates of the estrogen response in sheep (Greiss Jr et al). 1986; **154**:831-8
Treatment of endometriosis (Lockhart Jr) (Letter). 1986; **154**:215-6

Ethics
The Golden Thread (Malkasian Jr). 1986; **154**:1285-90 (Pres. address)
Your morality or mine? An inquiry into the ethics of human reproduction (Hill). 1986; **154**:1173-80 (Pres. address)

Ethinyl estradiol
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44

Exchange transfusion
The effects of fetal exchange transfusion with a red blood cell substitute (Ambrose et al). 1986; **154**:667-74

Exercise
Cardiorespiratory fitness evaluation in climacteric women: Comparison of two methods (Notelovitz et al). 1986; **154**:1009-13
Moderate recreational running is associated with lowered salivary progesterone profiles in women (Ellison and Lager). 1986; **154**:1000-3
Plasma immunoreactive β-endorphin in exercise-associated amenorrhea (Laatikainen et al). 1986; **154**:94-7
Pulmonary responses to exercise in pregnancy (Artal et al). 1986; **154**:378-83
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64

External cephalic version
External cephalic version of the breech presentation under tocolysis (Morrison et al). 1986; **154**:900-3

Extracorporeal perfusion
Extracorporeal perfusion of the human uterus (Bulletti et al). 1986; **154**:683-8

F

Fallopian tube
Human fallopian tube contains placental protein 14 (Julkunen et al). 1986; **154**:1076-9
Primary carcinoma of the fallopian tube (Podratz et al). 1986; **154**:1319-26
Results of microsurgical treatment of tubal infertility and early second-look laparoscopy in the post–pelvic inflammatory disease patient: Implications for in vitro fertilization (Luber et al). 1986; **154**:1264-70
Tubal conservation in ectopic pregnancy: A study of 200 cases (Hallatt). 1986; **154**:1216-21

Family trait analysis
Family trait analysis: A case-control study of 43 women with endometriosis and their best friends (Lamb et al). 1986; **154**:596-601

Ferning
Amniotic fluid ferning in early gestation (Borten and Friedman). 1986; **154**:628-30

Fertility; *see* **Infertility**

Fertilization; *see also* **Embryo transfer; Infertility**
An analysis of the obstetric outcome of 125 consecutive pregnancies conceived in vitro and resulting in 100 deliveries (Andrews et al). 1986; **154**:848-54
The effects of enclomiphene and zuclomiphene citrates on mouse embryos fertilized in vitro and in vivo (Schmidt et al). 1986; **154**:727-36
Experience with intrauterine insemination for cervical factor and oligospermia (Hull et al). 1986; **154**:1333-8
An in vitro fertilization and embryo transfer pilot study: Treatment-dependent and treatment-independent pregnancies (Jarrell et al). 1986; **154**:231-4
An obstetric assessment of the first 100 births from the in vitro fertilization program at Clamart, France (Frydman et al). 1986; **154**:550-5
Results of microsurgical treatment of tubal infertility and early second-look laparoscopy in the post–pelvic inflammatory disease patient: Implications for in vitro fertilization (Luber et al). 1986; **154**:1264-70
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4

Fetal heart rate
Correlation of neonatal acid-base status with Apgar scores and fetal heart rate tracings (Page et al). 1986; **154**:1306-11
Effects of reduced uterine blood flow on accelerations and decelerations in heart rate of fetal sheep (Bocking et al). 1986; **154**:329-35
Fetal heart rate monitoring and neonatal mortality in the very preterm infant (Braithwaite et al). 1986; **154**:250-4
Fetal injury prior to labor: Does it happen? (Paul et al) 1986; **154**:1187-93
Fetal response to vibratory acoustic stimulation in periods of low heart rate reactivity and low activity (Ohel et al). 1986; **154**:619-21
The relationship between antepartum fetal heart rate, intrapartum fetal heart rate, and fetal acid-base status (Low et al). 1986; **154**:769-76
Relationship of baseline fetal heart rate to gestational age and fetal sex (Druzin et al). 1986; **154**:1102-3
Sequential nonstress testing with use of each fetus as its own control (Devoe et al). 1986; **154**:931-6
Sinusoidal fetal heart rate pattern after administration of nalbuphine hydrochloride: A case report (Feinstein et al). 1986; **154**:159-60

Fetal lung maturity
Amniotic fluid collagenase inhibitor: Correlation with gestational age and fetal lung maturity (Stricklin et al). 1986; **154**:134-9
Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity (Kogon et al). 1986; **154**:226-30
Effect of aminophylline on lung maturation in preterm rabbit fetuses (Cosmi et al). 1986; **154**:436-9
Effect of induced oligohydramnios on fetal lung development (King et al). 1986; **154**:823-30
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74

Fetomaternal hemorrhage
Fetomaternal hemorrhage associated with umbilical vein thrombosis (Hoag). 1986; **154**:1271-4
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9
α-Fetoprotein
Maternal serum α-fetoprotein and fetal autosomal trisomies (Doran et al). 1986; **154**:277-81
Fetus; *see also* **Chorionic villus; Fetal heart rate; Fetal lung maturity; Fetomaternal hemorrhage**
Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography (Copel et al). 1986; **154**:1121-32 (Curr. Dev.)
Corticotropin-releasing factor can stimulate gonadotropin secretion by human fetal pituitaries in superfusion (Blumenfeld et al). 1986; **154**:606-12
Decreased fetal cord prolactin concentration in diabetic pregnancies (Saltzman et al). 1986; **154**:1035-8
The effect of antenatal dexamethasone on maternal and fetal retinol-binding protein (Hustead and Zachman). 1986; **154**:203-5
The effect of electrical stimulation on behavioral states in the fetal lamb (Natale and Nasello-Paterson). 1986; **154**:321-8
Effect of maternal hyperketonemia in hyperglycemic pregnant ewes and their fetuses (Miodovnik et al). 1986; **154**:394-401
The effects of fetal exchange transfusion with a red blood cell substitute (Ambrose et al). 1986; **154**:667-74
Effects of reduced uterine blood flow on electrocortical activity, breathing, and skeletal muscle activity in fetal sheep (Bocking and Harding). 1986; **154**:655-62
Extracorporeal perfusion of the human uterus (Bulletti et al). 1986; **154**:683-8
Factors influencing nonstress test results in multiple gestations (Patkos et al). 1986; **154**:1107-8
Failure of nonstress test and Doppler-assessed umbilical arterial blood flow to detect imminent intrauterine death (Erskine et al). 1986; **154**:1109-10
Fetal cystic hygroma colli: Antenatal diagnosis, significance, and management (Garden et al). 1986; **154**:221-5
Fetal injury prior to labor: Does it happen? (Paul et al) 1986; **154**:1187-93
Fetal α-melanocyte–stimulating homone levels: No correlation with late fetal growth but increased with diabetes mellitus (Hassan et al). 1986; **154**:428-30
Fetal microcirculation of abnormal human placenta. I. Scanning electron microscopy of placental vascular casts from small for gestational age fetus (Lee and Yeh). 1986; **154**:1133-9
Fetal microcirculation of abnormal human placenta. II. Scanning electron microscopy of placental vascular casts from fetus with severe erythroblastosis fetalis (Lee and Yeh). 1986; **154**:1139-46
Fetal responses to maternal infusions of angiotensin II (Perales et al). 1986; **154**:195-203
Fetoplacental steroid metabolism in prolonged pregnancies (Reynolds et al). 1986; **154**:74-9
Incorporation of labeled ribonucleic acid precursors into maternal and fetal rat tissues during pregnancy (Dorko and Hayashi). 1986; **154**:801-5
Intravascular transfusion in utero: The percutaneous approach (Berkowitz et al). 1986; **154**:622-3
The length of the human umbilical cord in vertex and breech presentations (Soernes and Bakke). 1986; **154**:1086-7
Maternal, fetal, and newborn complications associated with newborn intracranial hemorrhage (Low et al). 1986; **154**:345-51
Maternal and fetal surveillance for older pregnant women (Schipul Jr et al) (Letter); (Kirz) (Reply). 1986; **154**:967-8
Maternal ovine placental vascular responses to adenosine (Landauer et al). 1986; **154**:1152-5
Maternal serum α-fetoprotein and fetal autosomal trisomies (Doran et al). 1986; **154**:277-81
Maternal-fetal ABO/Rh antigenic relationships and human fetal development (Hoff and Bixler). 1986; **154**:126-9
Oxygen consumption in fetal lambs after maternal administration of sodium pentobarbital (Rurak and Taylor). 1986; **154**:674-8
Physiologic changes in pregnant women and their fetuses during jet air travel (Huch et al). 1986; **154**:996-1000
Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3
The prenatal diagnosis of Robin anomalad (Pilu et al). 1986; **154**:630-2
Prostaglandin secretion by adrenal tissue of human anencephalic fetuses (Carr et al). 1986; **154**:373-8
Quantitative two-dimensional echocardiographic assessment of fetal cardiac growth (Shime et al). 1986; **154**:294-300
Relative placental size in growth-retarded infants (Woods) (Letter); (Teasdale) (Reply). 1986; **154**:1170
Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study (Herbst et al). 1986; **154**:814-22
A sonographic sign for fetal Down's syndrome (Defoort and Thiery) (Letter). 1986; **154**:1169-70
Squamous cells in the maternal pulmonary circulation (Clark et al). 1986; **154**:104-6
Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization (Seeds and Bowes Jr). 1986; **154**:1105-7
Fever
Lactation suppression and puerperal fever (Almeida and Kitay). 1986; **154**:940-1
Fibrocystic breast disease
Fibrocystic breast disease: Pathophysiology, pathomorphology, clinical picture, and management (Vorherr). 1986; **154**:161-79
Fibronectin
Predictive value of fibronectin levels in normotensive gravid women destined to become preeclamptic (Lazarchick et al). 1986; **154**:1050-2
Fistula
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6
Flora
Bacterial flora of the cervix in women using different methods of contraception (Haukkamaa et al). 1986; **154**:520-4
Microbial colonization of tailed and tailless intrauterine contraceptive devices: Influence of the mode of insertion in the rabbit (Jacques et al). 1986; **154**:648-55

Vaginal colonization with *Escherichia coli* in healthy women (Chow et al). 1986; **154**:120-6
The in vivo effect of amniotic fluid on endocervical microflora (Patterson et al). 1986; **154**:1111-2

Fluosol-DA
The effects of fetal exchange transfusion with a red blood cell substitute (Ambrose et al). 1986; **154**:667-74

Focal vulvitis
Focal vulvitis: A characteristic syndrome and cause of dyspareunia: Features, natural history, and management (Peckham et al). 1986; **154**:855-64

Folic acid
Folate deficiency presenting as pancytopenia in pregnancy (Solano Jr and Councell). 1986; **154**:1117-8

Follicle
An analysis of the effects of increasing doses of ionizing radiation to the exteriorized rat ovary on follicular development, atresia, and serum gonadotropin levels (Jarrell et al). 1986; **154**:306-9
Biochemical and physiologic characterization of follicle regulatory protein: A paracrine regulator of folliculogenesis (Ono et al). 1986; **154**:709-16
Histologic and hormonal documentation of the luteinized unruptured follicle syndrome (Schenken et al). 1986; **154**:839-47

Forceps
Reply to Dr. Emanuel Friedman (Kadar) (Letter). 1986; **154**:694-5

Fructosamine
Serum fructosamine: A screening test for diabetes in pregnancy (Roberts and Baker). 1986; **154**:1027-30

G

Gaucher's disease
Gaucher's disease in pregnancy associated with portal hypertension (Mazor et al). 1986; **154**:1119-20

Gender
Relationship of baseline fetal heart rate to gestational age and fetal sex (Druzin et al). 1986; **154**:1102-3

Genetics
Family trait analysis: A case-control study of 43 women with endometriosis and their best friends (Lamb et al). 1986; **154**:596-601

Genital herpes
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8

Gestational age; *see also* Prematurity
Amniotic fluid collagenase inhibitor: Correlation with gestational age and fetal lung maturity (Stricklin et al). 1986; **154**:134-9

Gestational diabetes; *see* Diabetes

Gestosis
Expanded toxemia syndrome or gestosis (Goodlin). 1986; **154**:1227-33

Glucocorticosteroid
Prostaglandin secretion by adrenal tissue of human anencephalic fetuses (Carr et al). 1986; **154**:373-8

Glucose; *see also* Diabetes
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Glucose threshold for macrosomia in pregnancy complicated by diabetes (Willman et al). 1986; **154**:470-5
Should a fifty-gram, one-hour plasma glucose screening test for gestational diabetes be administered in the fasting or fed state? (Coustan et al) 1986; **154**:1031-5
Uterine metabolism of the pregnant rabbit under chronic steady-state conditions (Johnson et al). 1986; **154**:1146-51

Glycoprotein
Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein (Mogensen et al) (Letter). 1986; **154**:1165-6

Goiter
Goiter in pregnancy (Hegedüs et al) (Letter); (Long et al) (Reply). 1986; **154**:1164

Gonadotropin
An analysis of the effects of increasing doses of ionizing radiation to the exteriorized rat ovary on follicular development, atresia, and serum gonadotropin levels (Jarrell et al). 1986; **154**:306-9
Corticotropin-releasing factor can stimulate gonadotropin secretion by human fetal pituitaries in superfusion (Blumenfeld et al). 1986; **154**:606-12
Elevated concentrations of the β-subunit of human chorionic gonadotropin and testosterone in the amniotic fluid of gestations of diabetic mothers (Barbieri et al). 1986; **154**:1039-43
Human chorionic gonadotropin in early normal and pathologic pregnancy (Steier et al). 1986; **154**:1091-4
Inhibition of human chorionic gonadotropin production by prolactin from term human trophoblast (Ho Yuen et al). 1986; **154**:336-40
Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Relationship between log of the human chorionic gonadotropin concentration and time period in early pregnancy (Kadar) (Letter); (Pittaway) (Reply). 1986; **154**:692-4

Gonadotropin-releasing hormone
Inhibition of gonadotropin-releasing hormone receptors in rat anterior pituitary monolayer cell cultures by danazol (Menon et al). 1986; **154**:362-72
Relationship of gonadotropin-releasing hormone, danazol, and prostaglandin blockade to ovarian enlargement and ascites formation of the ovarian hyperstimulation syndrome in the rabbit (Pride et al). 1986; **154**:1155-60
Treatment of severe androgen excess due to ovarian hyperthecosis with a long-acting gonadotropin-releasing hormone agonist (Steingold et al). 1986; **154**:1241-8

Graft
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6

Granulosa cell
Biochemical and physiologic characterization of follicle regulatory protein: A paracrine regulator of folliculogenesis (Ono et al). 1986; **154**:709-16

Group B β-hemolytic streptococcal sepsis
An obstetric approach to the prevention of early-onset group B β-hemolytic streptococcal sepsis (Minkoff and Mead). 1986; **154**:973-7

Growth hormone
Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3

Growth retardation
Fetal microcirculation of abnormal human placenta. I. Scanning electron microscopy of placental vascular casts from small for gestational age fetus (Lee and Yeh). 1986; **154**:1133-9
Relative placental size in growth-retarded infants (Woods) (Letter); (Teasdale) (Reply). 1986; **154**:1170

H

Hamman's syndrome
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9
Heart
Aortic function during normal human pregnancy (Hart et al). 1986; **154**:887-91
Cardiorespiratory fitness evaluation in climacteric women: Comparison of two methods (Notelovitz et al). 1986; **154**:1009-13
Cardiovascular alterations in severe pregnancy-induced hypertension: Effects of intravenous nitroglycerin coupled with blood volume expansion (Cotton et al). 1986; **154**:1053-9
Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography (Copel et al). 1986; **154**:1121-32 (Curr. Dev.)
Coronary artery disease in diabetic pregnancies (Reece et al). 1986; **154**:150-1
Effect of ritodrine on uteroplacental blood flow and cardiac output distribution in unanesthetized pregnant guinea pigs (van de Walle and Martin Jr). 1986; **154**:189-94
Estrogen use and cardiovascular disease (Henderson et al). 1986; **154**:1181-6
Multiple peripheral pulmonic stenosis in pregnancy (Landsberger and Grossman III). 1986; **154**:152-3
Quantitative two-dimensional echocardiographic assessment of fetal cardiac growth (Shime et al). 1986; **154**:294-300
Sinusoidal fetal heart rate pattern after administration of nalbuphine hydrochloride: A case report (Feinstein et al). 1986; **154**:159-60
Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women (Sánchez et al). 1986; **154**:910-3
Heat flux
Heat flux and oxygen consumption of the pregnant uterus (Rudelstorfer et al). 1986; **154**:462-70
Hegar's sign
Correct use of Hegar's sign (Speck) (Letter); (Munsick) (Reply). 1986; **154**:691-2
HELLP syndrome
Severe hypoglycemia associated with the HELLP syndrome (Mabie and Sibai) (Letter); (Egley) (Reply). 1986; **154**:211-2
Hematocolpos
Endometriosis in association with uterine anomaly (Sanfilippo et al). 1986; **154**:39-43
Hematocrit
Human platelet α-adrenergic receptors and responses during pregnancy: No change except that with differing hematocrit (Roberts et al). 1986; **154**:206-10
Hemicolectomy
Perforated adenocarcinoma of the appendix during pregnancy (Donnenfeld et al). 1986; **154**:637-8
Hemolytic disease of neonate; *see* **Rh isoimmunization**
β-Hemolytic streptococcal sepsis
An obstetric approach to the prevention of early-onset group B β-hemolytic streptococcal sepsis (Minkoff and Mead). 1986; **154**:973-7
Hemorrhage
Antenatal phenobarbital for the prevention of neonatal intracerebral hemorrhage (Shankaran et al). 1986; **154**:53-7
Fetomaternal hemorrhage associated with umbilical vein thrombosis (Hoag). 1986; **154**:1271-4
Is there a causal connection between motile rods, *Mobiluncus* species, and bleeding complications? (Larsson and Bergman). 1986; **154**:107-8
Maternal, fetal, and newborn complications associated with newborn intracranial hemorrhage (Low et al). 1986; **154**:345-51
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9
Hepatitis
Prevalence of hepatitis B surface antigen among women receiving prenatal care at the Palm Beach County Health Department (Malecki et al). 1986; **154**:625-6
Heredity
Family trait analysis: A case-control study of 43 women with endometriosis and their best friends (Lamb et al). 1986; **154**:596-601
Herpes simplex virus
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
Herpes zoster virus
Excretion of varicella–herpes zoster virus in breast milk (Frederick et al). 1986; **154**:1116-7
Hexoprenaline
Effect of hexoprenaline on uteroplacental blood flow in the pregnant rat (Lipshitz et al). 1986; **154**:310-4
Effect of long-term administration of β_2-sympathomimetic drug in the diet-restricted pregnant rat model (Lipshitz et al). 1986; **154**:314-7
Histoplasmosis
Meningoencephalitis caused by *Histoplasma capsulatum* complicating pregnancy (McGregor et al). 1986; **154**:925-31
Home glucose monitoring
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Hospitalization
Effects of maternal transport on admission patterns at a tertiary care center (Cowett et al). 1986; **154**:1098-100
A large community hospital's experience with an obstetrics-gynecology risk management committee: Quality assurance (Der Yuen). 1986; **154**:1206-10
Obstetric hospital stays by diagnosis related groups: A community-based analysis (Lagoe). 1986; **154**:873-8
Human papillomavirus; *see* **Papillomavirus**
Hydatidiform mole
Demonstration of myc and ras oncogene expression by hybridization in situ in hydatidiform mole and in the BeWo choriocarcinoma cell line (Sarkar et al). 1986; **154**:390-3
Epidemiology of hydatidiform mole during early gestation (Atrash et al). 1986; **154**:906-9
Occurrence of molar pregnancy in patients undergoing elective abortion: Comparison with other clinical presentations (Ho Yuen and Callegari). 1986; **154**:273-6

Hydrops fetalis
Hydrops fetalis and chromosomal trisomies (Landrum et al). 1986; **154**:1114-5
6-Hydroxydopamine
Circulatory responses to hypovolemia in the pregnant and nonpregnant sheep after pharmacologic sympathectomy (Tabsh et al). 1986; **154**:411-9
5-Hydroxytryptophan
Influence of sequential doses of 5-hydroxytryptophan on prolactin release (Sueldo et al). 1986; **154**:424-7
Hygroma
Fetal cystic hygroma colli: Antenatal diagnosis, significance, and management (Garden et al). 1986; **154**:221-5
Hyperbilirubinemia
Measurements of delta optical density at 450 nm in SS disease (Nelson) (Letter); (Lindsay and Lupo) (Reply). 1986; **154**:1166
Hyperglycemia; *see also* **Diabetes**
Glucose threshold for macrosomia in pregnancy complicated by diabetes (Willman et al). 1986; **154**:470-5
Hyperinsulinemia
Hyperinsulinemia in hyperthecosis of the ovaries (Nagamani et al). 1986; **154**:384-9
Hyperketonemia
Effect of maternal hyperketonemia in hyperglycemic pregnant ewes and their fetuses (Miodovnik et al). 1986; **154**:394-401
Hyperprolactinemia
Pergolide and bromocriptine for the treatment of patients with hyperprolactinemia (Kletzky et al). 1986; **154**:431-5
Hypertension
Cardiovascular alterations in severe pregnancy-induced hypertension: Effects of intravenous nitroglycerin coupled with blood volume expansion (Cotton et al). 1986; **154**:1053-9
Gaucher's disease in pregnancy associated with portal hypertension (Mazor et al). 1986; **154**:1119-20
Hypertensive diseases of pregnancy and parity (Gleicher et al). 1986; **154**:1044-9
The relation of angiotensin-converting enzyme to the pregnancy-induced hypertension–preeclampsia syndrome (Goldkrand and Fuentes). 1986; **154**:792-800
The relationship between abortion in the first pregnancy and development of pregnancy-induced hypertension in the subsequent pregnancy (Strickland et al). 1986; **154**:146-8
Role of intravenous nitroglycerin in the treatment of severe pregnancy-induced hypertension complicated by pulmonary edema (Cotton et al). 1986; **154**:91-3
Severe preeclampsia with persistent oliguria: Management of hemodynamic subsets (Clark et al). 1986; **154**:490-4
Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women (Sánchez et al). 1986; **154**:910-3
Uterine artery Doppler velocimetry in pregnant women with hypertension (Fleischer et al). 1986; **154**:806-13
Hyperthecosis
Hyperinsulinemia in hyperthecosis of the ovaries (Nagamani et al). 1986; **154**:384-9
Treatment of severe androgen excess due to ovarian hyperthecosis with a long-acting gonadotropin-releasing hormone agonist (Steingold et al). 1986; **154**:1241-8
Hypoglycemia
Severe hypoglycemia associated with the HELLP syndrome (Mabie and Sibai) (Letter); (Egley) (Reply). 1986; **154**:211-2
Hypokalemia
Electrocardiographic changes associated with ritodrine-induced maternal tachycardia and hypokalemia (Hendricks et al). 1986; **154**:921-3
Hypotension
Profound hypotension complicating magnesium therapy (Bourgeois et al). 1986; **154**:919-20
Hypovolemia
Circulatory responses to hypovolemia in the pregnant and nonpregnant sheep after pharmacologic sympathectomy (Tabsh et al). 1986; **154**:411-9
Hypoxia; *see also* **Fetal heart rate**
Effects of reduced uterine blood flow on accelerations and decelerations in heart rate of fetal sheep (Bocking et al). 1986; **154**:329-35
Physiologic changes in pregnant women and their fetuses during jet air travel (Huch et al). 1986; **154**:996-1000
The relationship between antepartum fetal heart rate, intrapartum fetal heart rate, and fetal acid-base status (Low et al). 1986; **154**:769-76
Hysterectomy
Are preoperative antibiotics helpful in abdominal hysterectomy? (Senior and Steigrad) 1986; **154**:1004-8
Cefotetan versus cefoxitin as prophylaxis in hysterectomy (Orr Jr et al). 1986; **154**:960-3 (Symposium)
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6

I

Imaging
Magnetic resonance imaging and placenta previa (Power et al). 1986; **154**:565-9
Immunoglobulin G
Immunoglobulin G subclasses and isoimmunized pregnancy outcome (Taslimi et al). 1986; **154**:1327-32
Impedance plethysmography
Leg static pressure values in pregnant women with iatrogenic pulmonary edema (Goodlin). 1986; **154**:634-5
In utero transfusion
Intravascular transfusion in utero: The percutaneous approach (Berkowitz et al). 1986; **154**:622-3
Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization (Seeds and Bowes Jr). 1986; **154**:1105-7
In vitro fertilization; *see* **Fertilization**
Incision
In defense of the vertical uterine incision (Goodlin) (Letter); (Jovanovic) (Reply). 1986; **154**:966-7
Finger extension of transverse uterine incision (Gerace) (Letter); (Jovanovic) (Reply). 1986; **154**:1168-9
Incompetent cervix
Ultrasound differentiation of the competent from the incompetent cervix: Prevention of preterm delivery (Michaels et al). 1986; **154**:537-46
Incontinence
Modified retropubic cystourethropexy (Goodno Jr and Powers). 1986; **154**:1211-5
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64
Indomethacin
Relationship of gonadotropin-releasing hormone, danazol, and prostaglandin blockade to ovarian enlargement and ascites formation of the ovarian hyperstimulation syndrome in the rabbit (Pride et al). 1986; **154**:1155-60

Induced labor
Preinduction cervical ripening with sequential use of prostaglandin E_2 gel (Prins et al). 1986; **154**:1275-9
Infant; *see also* **Neonate**
The influence of prolonged pregnancy on infant development at one and two years of age: A prospective controlled study (Shime et al). 1986; **154**:341-5
Midforceps deliveries: Long-term outcome of infants (Dierker Jr et al). 1986; **154**:764-8
Infection
Cefotetan in the treatment of obstetric and gynecologic infections (Poindexter III et al). 1986; **154**:946-50 (Symposium)
Cefotetan versus cefoxitin as prophylaxis in hysterectomy (Orr Jr et al). 1986; **154**:960-3 (Symposium)
Comparison of cefotetan and cefoxitin as prophylaxis in cesarean section (Varner et al). 1986; **154**:951-4 (Symposium)
Etiology of cervical inflammation (Paavonen et al). 1986; **154**:556-64
Further studies on genital mycoplasmis in intra-amniotic infection: Blood cultures and serologic response (Gibbs et al). 1986; **154**:717-26
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
Human papillomavirus infection of the cervix detected by cervicovaginal lavage and molecular hybridization: Correlation with biopsy results and Papanicolaou smear (Burk et al). 1986; **154**:982-9
Infective endocarditis in obstetric and gynecologic practice (Seaworth and Durack). 1986; **154**:180-8
Is there a causal connection between motile curved rods, *Mobiluncus* species, and bleeding complications? (Larsson and Bergman). 1986; **154**:107-8
Localization of *Chlamydia trachomatis* infection by direct immunofluorescence and culture in pelvic inflammatory disease (Kiviat et al). 1986; **154**:865-73
Microbial colonization of tailed and tailless intrauterine contraceptive devices: Influence of the mode of insertion in the rabbit (Jacques et al). 1986; **154**:648-55
Mobiluncus-specific antibodies in a postoperative infection (Larsson et al) (Letter). 1986; **154**:1167-8
An obstetric approach to the prevention of early-onset group B β-hemolytic streptococcal sepsis (Minkoff and Mead). 1986; **154**:973-7
Protease production by microorganisms associated with reproductive tract infection (McGregor et al). 1986; **154**:109-14
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Residues of pelvic inflammatory disease in intrauterine device users: A result of the intrauterine device or *Chlamydia trachomatis* infection? (Guderian and Trobough). 1986; **154**:497-503
Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients (McGregor et al). 1986; **154**:955-60 (Symposium)
Infertility; *see also* **Fertilization**
Analysis of sequential treatment protocols for endometriosis-associated infertility (Olive and Lee). 1986; **154**:613-9
Conservative treatment of ectopic pregnancy with methotrexate (Ory et al). 1986; **154**:1299-1306
Upper genital tract changes and infertility in diethylstilbestrol-exposed women (Kaufman et al). 1986; **154**:1312-8
Inflammation; *see also* **Infection**
Etiology of cervical inflammation (Paavonen et al). 1986; **154**:556-64
Inheritance
Family trait analysis: A case-control study of 43 women with endometriosis and their best friends (Lamb et al). 1986; **154**:596-601
Insemination; *see also* **Embryo transfer; Fertilization**
Experience with intrauterine insemination for cervical factor and oligospermia (Hull et al). 1986; **154**:1333-8
Insulin
The current role of daily serum estriol monitoring in the insulin-dependent pregnant diabetic woman (Ray et al). 1986; **154**:1257-63
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Hyperinsulinemia in hyperthecosis of the ovaries (Nagamani et al). 1986; **154**:384-9
Intracranial hemorrhage
Antenatal phenobarbital for the prevention of neonatal intracerebral hemorrhage (Shankaran et al). 1986; **154**:53-7
Maternal, fetal, and newborn complications associated with newborn intracranial hemorrhage (Low et al). 1986; **154**:345-51
Intraepithelial neoplasia
Cervical intraepithelial neoplasia and condyloma: An analysis of diagnostic accuracy of posttreatment follow-up methods (Falcone and Ferenczy). 1986; **154**:260-4
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Treatment of cervical intraepithelial neoplasia with electrocautery: A report of 776 cases (Deigen et al). 1986; **154**:255-9
Intrauterine death; *see* **Mortality**
Intrauterine device
Bacterial flora of the cervix in women using different methods of contraception (Haukkamaa et al). 1986; **154**:520-4
Microbial colonization of tailed and tailless intrauterine contraceptive devices: Influence of the mode of insertion in the rabbit (Jacques et al). 1986; **154**:648-55
Residues of pelvic inflammatory disease in intrauterine device users: A result of the intrauterine device or *Chlamydia trachomatis* infection? (Guderian and Trobough). 1986; **154**:497-503
Intrauterine transfusion
Intravascular transfusion in utero: The percutaneous approach (Berkowitz et al). 1986; **154**:622-3
Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization (Seeds and Bowes Jr). 1986; **154**:1105-7
Intussusception
Postoperative intussusception after vaginal vault suspension (Hunter et al). 1986; **154**:633-4
Ionizing radiation
An analysis of the effects of increasing doses of ionizing radiation to the exteriorized rat ovary on follicular development, atresia, and serum gonadotropin levels (Jarrell et al). 1986; **154**:306-9

Isoimmunization; *see also* Rh isoimmunization
Immunoglobulin G subclasses and isoimmunized pregnancy outcome (Taslimi et al). 1986; **154**:1327-32
Isoproterenol
Myometrial desensitization to continuous but not to intermittent β-adrenergic agonist infusion in the sheep (Casper and Lye). 1986; **154**:301-5
Items
Items. 1986; **154**:220, 476, 697-8, 972, 1172, 1371-91

J

Jehovah's Witnesses
Blood transfusions and Jehovah's Witnesses: Medical and legal issues in obstetrics and gynecology (Sacks and Koppes). 1986; **154**:483-6 (Clin. Opinion)
Jet air travel
Physiologic changes in pregnant women and their fetuses during jet air travel (Huch et al). 1986; **154**:996-1000

K

Kegel exercise
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64
Kell sensitization
Kell sensitization in pregnancy (Caine and Mueller-Heubach). 1986; **154**:85-90
Ketone
Effect of maternal hyperketonemia in hyperglycemic pregnant ewes and their fetuses (Miodovnik et al). 1986; **154**:394-401
17-Ketoreductase
Male pseudohermaphroditism due to 17-ketoreductase deficiency: Report of a case without gynecomastia and without vaginal pouch (Caufriez). 1986; **154**:148-9
Kidney
Antenatal diagnosis of renal anomalies with ultrasound. IV. Bilateral multicystic kidney disease (D'Alton et al). 1986; **154**:532-7
Prenatal diagnosis of fetal renal mesoblastic nephroma (Apuzzio et al). 1986; **154**:636-7
Septic shock with renal failure after chorionic villus sampling (Barela et al). 1986; **154**:1100-2
Kleihauer-Betke test
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9

L

Labor; *see also* Delivery
Abdominal rescue after entrapment of the aftercoming head (Iffy et al). 1986; **154**:623-4
The effects of oral administration of progesterone for premature labor (Erny et al). 1986; **154**:525-9
Preinduction cervical ripening with sequential use of prostaglandin E_2 gel (Prins et al). 1986; **154**:1275-9
Preterm labor: Its diagnosis and management (Gonik and Creasy). 1986; **154**:3-8 (Clin. Opinion)
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9
Lactate
Uterine metabolism of the pregnant rabbit under chronic steady-state conditions (Johnson et al). 1986; **154**:1146-51
Lactation; *see* Breast-feeding
Lactogen
Blunted response of maternal ovine placental lactogen levels to arginine stimulation after single umbilical artery ligation in pregnant sheep (Newnham et al). 1986; **154**:663-6
Langerhans' cell
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Laparoscopy
Results of microsurgical treatment of tubal infertility and early second-look laparoscopy in the post–pelvic inflammatory disease patient: Implications for in vitro fertilization (Luber et al). 1986; **154**:1264-70
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4
Laparotomy
CA 125 surveillance and second-look laparotomy in ovarian carcinoma (Atack et al). 1986; **154**:287-9
Staging laparotomy in early epithelial ovarian carcinoma (Helewa et al). 1986; **154**:282-6
Laser
Toxic shock syndrome following carbon dioxide laser treatment of genital tract condyloma acuminatum (Bowen et al). 1986; **154**:145-6
Lecithin/sphingomyelin ratio; *see also* Respiratory distress syndrome
Effect of acetone precipitation on the clinical prediction of respiratory distress syndrome when utilizing amniotic fluid lecithin/sphingomyelin ratios (Hobson et al). 1986; **154**:1023-6
Legal issues
Blood transfusions and Jehovah's Witnesses: Medical and legal issues in obstetrics and gynecology (Sacks and Koppes). 1986; **154**:483-6 (Clin. Opinion)
Letters
Letters. 1986; **154**:211-7, 689-95, 964-70, 1164-70
Leukocyte-rich erythrocytes
Transfusions of leukocyte-rich erythrocyte concentrates: A successful treatment in selected cases of habitual abortion (Unander and Lindholm). 1986; **154**:516-20
Liability
The Golden Thread (Malkasian Jr). 1986; **154**:1285-90 (Pres. address)
Lipoprotein
The effect of dehydroepiandrosterone sulfate on de novo and low-density lipoprotein–stimulated progesterone secretion by human choriocarcinoma JEG-3 cells (Moise et al). 1986; **154**:1080-5
Lung; *see also* Fetal lung maturity; Respiratory distress syndrome
Effect of induced oligohydramnios on fetal lung development (King et al). 1986; **154**:823-30
Leg static pressure values in pregnant women with iatrogenic pulmonary edema (Goodlin). 1986; **154**:634-5
Pulmonary responses to exercise in pregnancy (Artal et al). 1986; **154**:378-83
Squamous cells in the maternal pulmonary circulation (Clark et al). 1986; **154**:104-6
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9
Lupus anticoagulant
Lupus anticoagulant and pregnancy (Spitz et al) (Letter). 1986; **154**:1169

Luteinizing hormone
Histologic and hormonal documentation of the luteinized unruptured follicle syndrome (Schenken et al). 1986; **154**:839-47
Inhibition of gonadotropin-releasing hormone receptors in rat anterior pituitary monolayer cell cultures by danazol (Menon et al). 1986; **154**:362-72
Modulation of luteinizing hormone immunoreactivity and bioactivity by dopamine but not norepinephrine in women (Barnes et al). 1986; **154**:445-50

Luteotropic hormone
Human ovarian oxytocin: Its source and relationship to steroid hormones (Dawood and Khan-Dawood). 1986; **154**:756-63

Lymphangiography
The role of lymphangiography in vulvar carcinoma (Weiner et al). 1986; **154**:1073-5

M

Macrophage
Peritoneal fluid in patients with and without endometriosis: Prostanoids and macrophages and their effect on the spermatozoa penetration assay (Chacho et al). 1986; **154**:1290-9

Macrosomia; *see also* **Diabetes**
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Glucose threshold for macrosomia in pregnancy complicated by diabetes (Willman et al). 1986; **154**:470-5

Magnesium sulfate
Profound hypotension complicating magnesium therapy (Bourgeois et al). 1986; **154**:919-20

Magnetic resonance imaging
Magnetic resonance imaging and placenta previa (Power et al). 1986; **154**:565-9

Male pseudohermaphroditism
Male pseudohermaphroditism due to 17-ketoreductase deficiency: Report of a case without gynecomastia and without vaginal pouch (Caufriez). 1986; **154**:148-9

Malignancy
Ultrasonographic evidence of uterine malignancy in the postmenopausal uterus (Chambers and Unis). 1986; **154**:1194-9

Media
An evaluation of different media for the zona-free hamster egg penetration test (Mortimer). 1986; **154**:351-4

Medroxyprogesterone acetate
Biochemical and histologic effects of sequential estrogen/progestin therapy on the endometrium of postmenopausal women (Gibbons et al). 1986; **154**:455-61

α-Melanocyte–stimulating hormone level
Fetal α-melanocyte–stimulating hormone levels: No correlation with late fetal growth but increased with diabetes mellitus (Hassan et al). 1986; **154**:428-30

Membranes
The effect of antenatal dexamethasone administration on the prevention of respiratory distress syndrome in preterm gestations with premature rupture of membranes (Morales et al). 1986; **154**:591-5
Effect of induced oligohydramnios on fetal lung development (King et al). 1986; **154**:823-30
A retrospective study on the effects of steroid administration and prolongation of the latent phase in patients with preterm premature rupture of the membranes (Arias et al). 1986; **154**:1059-63

Meningoencephalitis
Meningoencephalitis caused by *Histoplasma capsulatum* complicating pregnancy (McGregor et al). 1986; **154**:925-31

Menopause
Biochemical and histologic effects of sequential estrogen/progestin therapy on the endometrium of postmenopausal women (Gibbons et al). 1986; **154**:456-61
Cardiorespiratory fitness evaluation in climacteric women: Comparison of two methods (Notelovitz et al). 1986; **154**:1009-13
Estrogen use and cardiovascular disease (Henderson et al). 1986; **154**:1181-6
Ultrasonographic evidence of uterine malignancy in the postmenopausal uterus (Chambers and Unis). 1986; **154**:1194-9

Menstrual cycle
Basal and forskolin-stimulated cyclic adenosine monophosphate in intact human platelets during the menstrual cycle (Pansini et al). 1986; **154**:679-82
Variability and selectivity of anterior pituitary response to dopamine agonists throughout the normal menstrual cycle (Kletzky and Shangold). 1986; **154**:362-7

Mesoblastic nephroma
Prenatal diagnosis of fetal renal mesoblastic nephroma (Apuzzio et al). 1986; **154**:636-7

Metabolism
Fetoplacental steroid metabolism in prolonged pregnancies (Reynolds et al). 1986; **154**:74-9
Uterine metabolism of the pregnant rabbit under chronic steady-state conditions (Johnson et al). 1986; **154**:1146-51

Metastasis
Human papillomavirus deoxyribonucleic acid in cervical carcinoma from primary and metastatic sites (Lancaster et al). 1986; **154**:115-9
Staging laparotomy in early epithelial ovarian carcinoma (Helewa et al). 1986; **154**:282-6

Methotrexate
Conservative treatment of ectopic pregnancy with methotrexate (Ory et al). 1986; **154**:1299-1306

Metronidazole
Is there a causal connection between motile curved rods, *Mobiluncus* species, and bleeding complications? (Larsson and Bergman). 1986; **154**:107-8

Microcirculation
Fetal microcirculation of abnormal human placenta. I. Scanning electron microscopy of placental vascular casts from small for gestational age fetus (Lee and Yeh). 1986; **154**:1133-9
Fetal microcirculation of abnormal human placenta. II. Scanning electron microscopy of placental vascular casts from fetus with severe erythroblastosis fetalis (Lee and Yeh). 1096; **154**:1139-46

Microsurgery
Microsurgical reversal of sterilization: A six-year study (Spivak et al). 1986; **154**:355-61

Midforceps
Midforceps deliveries: Long-term outcome of infants (Dierker Jr et al). 1986; **154**:764-8
Reply to Dr. Emanuel Friedman (Kadar) (Letter). 1986; **154**:694-5

Midwifery
The perinatal and economic impact of prenatal care in a low-socioeconomic population (Moore et al). 1986;, **154**:29-33

Milk; *see also* Breast-feeding
Excretion of varicella–herpes zoster virus in breast milk (Frederick et al). 1986; **154**:1116-7
M-mode echocardiography
Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women (Sánchez et al). 1986; **154**:910-3
Mobiluncus
Is there a causal connection between motile curved rods, *Mobiluncus* species, and bleeding complications? (Larsson and Bergman). 1986; **154**:107-8
Mobiluncus-specific antibodies in a postoperative infection (Larsson et al) (Letter). 1986; **154**:1167-8
Mole; *see* Hydatidiform mole
Monitoring
Fetal heart rate monitoring and neonatal mortality in the very preterm infant (Braithwaite et al). 1986; **154**: 250-4
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Morality; *see* Ethics
Mortality
Birth asphyxia, trauma, and mortality in twins: Has cesarean section improved outcome? (Bell et al). 1986; **154**: 235-9
Failure of nonstress test and Doppler-assessed umbilical arterial blood flow to detect imminent intrauterine death (Erskine et al). 1096; **154**:1109-10
Fetal heart rate monitoring and neonatal mortality in the very preterm infant (Braithwaite et al). 1986; **154**: 250-4
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
Mucus
The tumor marker CA 125 is a common constituent of normal cervical mucus (de Bruijn et al). 1986; **154**:1088-91
Multicystic kidney disease
Antenatal diagnosis of renal anomalies with ultrasound. IV. Bilateral multicystic kidney disease (D'Alton et al). 1986; **154**:532-7
Mycoplasma
Further studies on genital mycoplasmas in intra-amniotic infection: Blood cultures and serologic response (Gibbs et al). 1986; **154**:717-26
Myometrium
α-Adrenergic receptors in human myometrium during pregnancy (Berg et al). 1986; **154**:601-6
Myometrial desensitization to continuous but not to intermittent β-adrenergic agonist infusion in the sheep (Casper and Lye). 1986; **154**:301-5
Myosin
Pharmacologic levels of nitrendipine do not affect actin-myosin interaction in the human uterus and placenta (Sakamoto and Huszar). 1986; **154**:402-7

N

Nalbuphine hydrochloride
Sinusoidal fetal heart rate pattern after administration of nalbuphine hydrochloride: A case report (Feinstein et al). 1986; **154**:159-60
Naloxone
Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Neonate
Antenatal phenobarbital for the prevention of neonatal intracerebral hemorrhage (Shankaran et al). 1986; **154**: 53-7
Breast-feeding in thrombocytopenic neonates secondary to maternal autoimmune thrombocytopenic purpura (Meschengieser and Lazzari) (Letter); (Martin Jr) (Reply). 1986; **154**:1166-7
Correlation of neonatal acid-base status with Apgar scores and fetal heart rate tracings (Page et al). 1986; **154**:1306-11
Effects of maternal transport on admission patterns at a tertiary care center (Cowett et al). 1986; **154**:1098-100
Fetal heart rate monitoring and neonatal mortality in the very preterm infant (Braithwaite et al). 1986; **154**:250-4
Gestational diabetes: Impact of home glucose monitoring on neonatal birth weight (Goldberg et al). 1986; **154**:546-50
Immunoglobulin G subclasses and isoimmunized pregnancy outcome (Taslimi et al). 1986; **154**:1327-32
Influence of breast-feeding on the restoration of the low serum concentration of vitamin E and β-carotene in the newborn infant (Ostrea Jr et al). 1986; **154**:1014-7
Maternal, fetal, and newborn complications associated with newborn intracranial hemorrhage (Low et al). 1986; **154**:345-51
Neonatal alloimmune thrombocytopenic purpura: A case report (Deaver et al). 1986; **154**:153-5
An obstetric approach to the prevention of early-onset group B β-hemolytic streptococcal sepsis (Minkoff and Mead). 1986; **154**:973-7
Perinatal events and cerebral palsy (Hensleigh et al). 1986; **154**:978-81
Relative placental size in growth-retarded infants (Woods) (Letter); (Teasdale) (Reply). 1986; **154** 1170
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74
Neoplasia; *see also* Carcinoma
Cervical intraepithelial neoplasia and condyloma: An analysis of diagnostic accuracy of posttreatment follow-up methods (Falcone and Ferenczy). 1986; **154**:260-4
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Testosterone levels and androgen-producing neoplasms (Meldrum) (Letter); (Friedman) (Reply). 1986; **154**: 965-6
Treatment of cervical intraepithelial neoplasia with electrocautery: A report of 776 cases (Deigen et al). 1986; **154**:255-9
Nephroma
Prenatal diagnosis of fetal renal mesoblastic nephroma (Apuzzio et al). 1986; **154**:636-7
Neutropenia
Ritodrine-induced neutropenia (Wang-Cheng and Davidson). 1986; **154**:924-5
Newborn infant; *see* Neonate
Nifedipine
The effect of a calcium channel blocker (nifedipine) on uterine blood flow in the pregnant goat (Veille et al). 1986; **154**:1160-3
Nitrendipine
Pharmacologic levels of nitrendipine do not affect actin-myosin interaction in the human uterus and placenta (Sakamoto and Huszar). 1986; **154**:402-7

Nitroglycerin
Cardiovascular alterations in severe pregnancy-induced hypertension: Effects of intravenous nitroglycerin coupled with blood volume expansion (Cotton et al). 1986; **154**:1053-9
Role of intravenous nitroglycerin in the treatment of severe pregnancy-induced hypertension complicated by pulmonary edema (Cotton et al). 1986; **154**:91-3
Norepinephrine
Modulation of luteinizing hormone immunoreactivity and bioactivity by dopamine but not norepinephrine in women (Barnes et al). 1986; **154**:445-50
Plasma catecholamine responses to physiologic stimuli in normal human pregnancy (Barron et al). 1986; **154**:80-4
Nubain; *see* **Nalbuphine hydrochloride**

O

Obesity
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Prepregnancy weight, weight gain, and birth weight (Abrams and Laros Jr). 1986; **154**:503-9
Obstetric outcome
An analysis of the obstetric outcome of 125 consecutive pregnancies conceived in vitro and resulting in 100 deliveries (Andrews et al). 1986; **154**:848-54
An obstetric assessment of the first 100 births from the in vitro fertilization program at Clamart, France (Frydman et al). 1986; **154**:550-5
Ultrasound evaluation of amniotic fluid: Outcome of pregnancies with severe oligohydramnios (Bastide et al). 1986; **154**:895-900
Oligohydramnios
Effect of induced oligohydramnios on fetal lung development (King et al). 1986; **154**:823-30
Ultrasound evaluation of amniotic fluid: Outcome of pregnancies with severe oligohydramnios (Bastide et al). 1986; **154**:895-900
Oligospermia
Experience with intrauterine insemination for cervical factor and oligospermia (Hull et al). 1986; **154**:1333-8
Oliguria
Severe preeclampsia with persistent oliguria: Management of hemodynamic subsets (Clark et al). 1986; **154**:490-4
Omental graft
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6
Oncogene
Demonstration of myc and ras oncogene expression by hybridization in situ in hydatidiform mole and in the BeWo choriocarcinoma cell line (Sarkar et al). 1986; **154**:390-3
Oocyte
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4
Opioid
Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Oral contraceptive; *see also* **specific agent**
Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Ovary
An analysis of the effects of increasing doses of ionizing radiation to the exteriorized rat ovary on follicular development, atresia, and serum gonadotropin levels (Jarrell et al). 1986; **154**:306-9
CA 125 surveillance and second-look laparotomy in ovarian carcinoma (Atack et al). 1986; **154**:287-9
A comparison of three techniques for ovarian reconstruction (Oelsner et al). 1986; **154**:569-72
Correlation of the ultrasonic appearance of the ovaries in polycystic ovarian disease and the clinical, hormonal, and laparoscopic findings (el Tabbakh et al). 1986; **154**: 892-5
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Hyperinsulinemia in hyperthecosis of the ovaries (Nagamani et al). 1986; **154**:384-9
Ovarian cancer in the elderly: An analysis of surveillance, epidemiology, and end results program data (Yancik et al). 1986; **154**:639-47 (Curr. Dev.)
Ovarian carcinoma of low malignant potential: Staging and treatment (Nation and Krepart). 1986; **154**:290-3
Ovarian pregnancy with a contralateral corpus luteum: Case report (Check and Chase). 1986; **154**:155-6
Relationship of gonadotropin-releasing hormone, danazol, and prostaglandin blockade to ovarian enlargement and ascites formation of the ovarian hyperstimulation syndrome in the rabbit (Pride et al). 1986; **154**:1155-60
Staging laparotomy in early epithelial ovarian carcinoma (Helewa et al). 1986; **154**:282-6
Treatment of severe androgen excess due to ovarian hyperthecosis with a long-acting gonadotropin-releasing hormone agonist (Steingold et al). 1986; **154**:1241-8
The tumor marker CA 125 is a common constituent of normal cervical mucus (de Bruijn et al). 1986; **154**:1088-91
Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein (Mogensen et al) (Letter). 1986; **154**:1165-6
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4
Ovulation
Histologic and hormonal documentation of the luteinized unruptured follicle syndrome (Schenken et al). 1986; **154**:839-47
Oxygen; *see also* **Hypoxia**
Fetal responses to maternal infusions of angiotensin II (Perales et al). 1986; **154**:195-203
Heat flux and oxygen consumption of the pregnant uterus (Rudelstorfer et al). 1986; **154**:462-70
Oxygen consumption in fetal lambs after maternal administration of sodium pentobarbital (Rurak and Taylor). 1986; **154**:674-8
Oxytocin
Human ovarian oxytocin: Its source and relationship to steroid hormones (Dawood and Khan-Dawood). 1986; **154**:756-63

P

Pacific Coast Obstetrical and Gynecological Society
Transactions of the fifty-second annual meeting of the Pacific Coast Obstetrical and Gynecological Society. 1986; **154**:1173-1284

Pain
Endometriosis in association with uterine anomaly (Sanfilippo et al). 1986; **154**:39-43
Pancytopenia
Folate deficiency presenting as pancytopenia in pregnancy (Solano Jr and Councell). 1986; **154**:1117-8
Papanicolaou smear
An analysis of the factors involved in the colposcopic evaluation of 2194 patients with abnormal Papanicolaou smears (Wetrich). 1986; **154**:1339-49
Human papillomavirus infection of the cervix detected by cervicovaginal lavage and molecular hybridization: Correlation with biopsy results and Papanicolaou smear (Burk et al). 1986; **154**:982-9
Papers
Papers of the Society for Gynecologic Investigation. 1986; **154**:362-475
Papillomavirus
Human papillomavirus deoxyribonucleic acid in cervical carcinoma from primary and metastatic sites (Lancaster et al). 1986; **154**:115-9
Human papillomavirus infection of the cervix detected by cervicovaginal lavage and molecular hybridization: Correlation with biopsy results and Papanicolaou smear (Burk et al). 1986; **154**:982-9
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15
Paracrine regulator
Biochemical and physiologic characterization of follicle regulatory protein: A paracrine regulator of folliculogenesis (Ono et al). 1986; **154**:709-16
Parity
The relationship between abortion in the first pregnancy and development of pregnancy-induced hypertension in the subsequent pregnancy (Strickland et al). 1986; **154**:146-8
Parlodel; *see* **Bromocriptine**
Parturition; *see* **Delivery**
Peer review
A large community hospital's experience with an obstetrics-gynecology risk management committee: Quality assurance (Der Yuen). 1986; **154**:1206-10
Pelvic infection; *see* **Infection; Pelvic inflammatory disease**
Pelvic inflammatory disease
Cefotetan in the treatment of obstetric and gynecologic infections (Poindexter III et al). 1986; **154**:946-50 (Symposium)
Localization of *Chlamydia trachomatis* infection by direct immunofluorescence and culture in pelvic inflammatory disease (Kiviat et al). 1986; **154**:865-73
Residues of pelvic inflammatory disease in intrauterine device users: A result of the intrauterine device or *Chlamydia trachomatis* infection? (Guderian and Trobough). 1986; **154**:497-503
Results of microsurgical treatment of tubal infertility and early second-look laparoscopy in the post–pelvic inflammatory disease patient: Implications for in vitro fertilization (Luber et al). 1986; **154**:1264-70
Serum C-reactive protein determination in acute pelvic inflammatory disease (Lehtinen et al). 1986; **154**:158-9
Penis
Colposcopy in the diagnosis of penile condyloma (Sedlacek et al). 1986; **154**:494-6
Pentobarbital
Oxygen consumption in fetal lambs after maternal administration of sodium pentobarbital (Rurak and Taylor). 1986; **154**:674-8
Percutaneous umbilical sampling
Percutaneous umbilical sampling in immune thrombocytopenic purpura (Sacks) (Letter); (Hobbins et al) (Reply). 1986; **154**:214-5
Pergolide
Pergolide and bromocriptine for the treatment of patients with hyperprolactinemia (Kletzky et al). 1986; **154**:431-5
Pericarditis
Constrictive pericarditis and pregnancy (Sachs et al). 1986; **154**:156-7
Perinatal morbidity
Perinatal events and cerebral palsy (Hensleigh et al). 1986; **154**:978-81
Peritoneal fluid
Peritoneal fluid in patients with and without endometriosis: Prostanoids and macrophages and their effect on the spermatozoa penetration assay (Chacho et al). 1986; **154**:1290-9
Pharmacologic sypathectomy
Circulatory responses to hypovolemia in the pregnant and nonpregnant sheep after pharmacologic sympathectomy (Tabsh et al). 1986; **154**:411-9
Phenobarbital
Antenatal phenobarbital for the prevention of neonatal intracerebral hemorrhage (Shankaran et al). 1986; **154**:53-7
Phosphatidylcholine phosphorus and phosphatidylglycerol
Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity (Kogon et al). 1986; **154**:226-30
Effect of aminophylline on lung maturation in preterm rabbit fetuses (Cosmi et al). 1986; **154**:436-9
Phospholipid
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74
Pituitary
Corticotropin-releasing factor can stimulate gonadotropin secretion by human fetal pituitaries in superfusion (Blumenfeld et al). 1986; **154**:606-12
Inhibition of gonadotropin-releasing hormone receptors in rat anterior pituitary monolayer cell cultures by danazol (Menon et al). 1986; **154**:362-72
Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Variability and selectivity of anterior pituitary response to dopamine agonists throughout the normal menstrual cycle (Kletzky and Shangold). 1986; **154**:362-7
Placenta
Blunted response of maternal ovine placental lactogen levels to arginine stimulation after single umbilical artery ligation in pregnant sheep (Newnham et al). 1986; **154**:663-6
Effect of hexoprenaline on uteroplacental blood flow in the pregnant rat (Lipshitz et al). 1986; **154**:310-4
Effect of long-term administration of β_2-sympathomimetic drug in the diet-restricted pregnant rat model (Lipshitz et al). 1986; **154**:314-7
The effects of fetal exchange transfusion with a red blood cell substitute (Ambrose et al). 1986; **154**:667-74

Fetal microcirculation of abnormal human placenta. I. Scanning electron microscopy of placental vascular casts from small for gestational age fetus (Lee and Yeh). 1986; **154**:1133-9

Fetal microcirculation of abnormal human placenta. II. Scanning electron microscopy of placental vascular casts from fetus with severe erythroblastosis fetalis (Lee and Yeh). 1986; **154**:1139-46

Fetoplacental steroid metabolism in prolonged pregnancies (Reynolds et al). 1986; **154**:74-9

Human fallopian tube contains placental protein 14 (Julkunen et al). 1986; **154**:1076-9

Incorporation of labeled ribonucleic acid precursors into maternal and fetal rat tissues during pregnancy (Dorko and Hayashi). 1986; **154**:801-5

Maternal ovine placental vascular responses to adenosine (Landauer et al). 1986; **154**:1152-5

Pharmacologic levels of nitrendipine do not affect actin-myosin interaction in the human uterus and placenta (Sakamoto and Huszar). 1986; **154**:402-7

Placental prostacyclin production in normal and toxemic pregnancies (Jeremy et al) (Letter); (Walsh) (Reply). 1986; **154**:212-4

Relative placental size in growth-retarded infants (Woods) (Letter); (Teasdale) (Reply). 1986; **154**:1170

Placenta previa

Magnetic resonance imaging and placenta previa (Power et al). 1986; **154**:565-9

Plasma

Partial purification of relaxin from human seminal plasma (Weiss et al). 1986; **154**:749-55

Plasma catecholamine responses to physiologic stimuli in normal human pregnancy (Barron et al). 1986; **154**:80-4

Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3

Plasma immunoreactive β-endorphin in exercise-associated amenorrhea (Laatikainen et al). 1986; **154**:94-7

Predictive value of fibronectin levels in normotensive gravid women destined to become preeclamptic (Lazarchick et al). 1986; **154**:1050-2

Sodium excretion in human pregnancy: A role for arginine vasopressin (Brown and Gallery). 1986; **154**:914-9

Platelet

Basal and forskolin-stimulated cyclic adenosine monophosphate in intact human platelets during the menstrual cycle (Pansini et al). 1986; **154**:679-82

An epidemic of maternal thrombocytopenia associated with elevated antiplatelet antibody (Hart et al). 1986; **154**:878-83

Human platelet α-adrenergic receptors and responses during pregnancy: No change except that with differing hematocrit (Roberts et al). 1986; **154**:206-10

Longitudinal study of platelet indices during normal pregnancy (Tygart et al). 1986; **154**:883-7

Plethysmography

Leg static pressure values in pregnant women with iatrogenic pulmonary edema (Gocdlin). 1986; **154**:634-5

Pneumomediastinum

Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9

Pneumothorax

Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9

Polycystic ovary

Correlation of the ultrasonic appearance of the ovaries in polycystic ovarian disease and the clinical, hormonal, and laparoscopic findings (el Tabbakh et al). 1986; **154**:892-5

Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44

Polyhydramnios

Ultrasound evaluation of polyhydramnios and twin pregnancy (Hashimoto et al). 1986; **154**:1069-72

Portal hypertension

Gaucher's disease in pregnancy associated with portal hypertension (Mazor et al). 1986; **154**:1119-20

Postdate pregnancy; *see* **Postmaturity**

Postmaturity

Biophysical profile scoring in the management of the postterm pregnancy: An analysis of 307 patients (Johnson et al). 1986; **154**:269-73

Fetoplacental steroid metabolism in prolonged pregnancies (Reynolds et al). 1986; **154**:74-9

The influence of prolonged pregnancy on infant development at one and two years of age: A prospective controlled study (Shime et al). 1986; **154**:341-5

Management of postdate pregnancy (Lagrew and Freeman). 1986; **154**:8-13 (Clin. Opinion)

Postmenopausal period; *see also* **Menopause**

Ultrasonographic evidence of uterine malignancy in the postmenopausal uterus (Chambers and Unis). 1986; **154**:1194-9

Postoperative complication

Mobiluncus-specific antibodies in a postoperative infection (Larsson et al) (Letter). 1986; **154**:1167-8

Postoperative intussusception after vaginal vault suspension (Hunter et al). 1986; **154**:633-4

Postpartum mood

Postpartum moods in men and women (Quadagno et al). 1986; **154**:1018-23

Postterm pregnancy; *see* **Postmaturity**

Potassium

Electrocardiographic changes associated with ritodrine-induced maternal tachycardia and hypokalemia (Hendricks et al). 1096; **154**:921-3

Preeclampsia; *see also* **Eclampsia**

Predictive value of fibronectin levels in normotensive gravid women destined to become preeclamptic (Lazarchick et al). 1986; **154**:1050-2

Profound hypotension complicating magnesium therapy (Bourgeois et al). 1986; **154**:919-20

The relation of angiotensin-converting enzyme to the pregnancy-induced hypertension–preeclampsia syndrome (Goldkrand and Fuentes). 1986; **154**:792-800

Relative placental size in growth-retarded infants (Woods) (Letter); (Teasdale) (Reply). 1986; **154**:1170

Severe preeclampsia with persistent oliguria: Management of hemodynamic subsets (Clark et al). 1986; **154**:490-4

Pregnancy

α-Adrenergic receptors in human myometrium during pregnancy (Berg et al). 1986; **154**:601-6

Amniotic fluid collagenase inhibitor: Correlation with ges-

tational age and fetal lung maturity (Stricklin et al). 1986; **154**:134-9
Amniotic fluid ferning in early gestation (Borten and Friedman). 1986; **154**:628-30
An analysis of the obstetric outcome of 125 consecutive pregnancies conceived in vitro and resulting in 100 deliveries (Andrews et al). 1986; **154**:848-54
Antenatal diagnosis of renal anomalies with ultrasound. IV. Bilateral multicystic kidney disease (D'Alton et al). 1986; **154**:532-7
Antenatal phenobarbital for the prevention of neonatal intracerebral hemorrhage (Shankaran et al). 1986; **154**: 53-7
Aortic function during normal human pregnancy (Hart et al). 1986; **154**:887-91
Assessment of uterine activity in ambulatory patients at high risk of preterm labor and delivery (Katz et al). 1986; **154**:44-7
Behavior of the squamocolumnar junction during normal pregnancy (Ganesh et al) (Letter). 1986; **154**:689-90
Blunted response of maternal ovine placental lactogen levels to arginine stimulation after single umbilical artery ligation in pregnant sheep (Newnham et al). 1986; **154**: 663-6
Caffeine consumption during pregnancy and association with late spontaneous abortion (Srisuphan and Bracken). 1986; **154**:14-20
Cardiovascular alterations in severe pregnancy-induced hypertension: Effects of intravenous nitroglycerin coupled with blood volume expansion (Cotton et al). 1986; **154**:1053-9
Chorionic villus sampling in continuing pregnancies. I. Low fetal loss rates in initial 109 cases (Elias et al). 1986; **154**:1349-52
Chorionic villus sampling in continuing pregnancies. II. Cytogenetic reliability (Martin et al). 1986; **154**:1353-62
Conservative treatment of ectopic pregnancy with methotrexate (Ory et al). 1986; **154**:1299-1306
Constrictive pericarditis and pregnancy (Sachs et al). 1986; **154**:156-7
Coronary artery disease in diabetic pregnancies (Reece et al). 1986; **154**:150-1
The current role of daily serum estriol monitoring in the insulin-dependent pregnant diabetic woman (Ray et al). 1986; **154**:1257-63
Cushing's syndrome in pregnancy: A case report and literature review (Koerten et al). 1986; **154**:626-8
Decreased fetal cord prolactin concentration in diabetic pregnancies (Saltzman et al). 1986; **154**:1035-8
The effect of a calcium channel blocker (nifedipine) on uterine blood flow in the pregnant goat (Veille et al). 1986; **154**:1160-3
The effect of antenatal dexamethasone on maternal and fetal retinol-binding protein (Hustead and Zachman). 1986; **154**:203-5
Elevated concentrations of the β-subunit of human chorionic gonadotropin and testosterone in the amniotic fluid of gestations of diabetic mothers (Barbieri et al). 1986; **154**:1039-43
An epidemic of maternal thrombocytopenia associated with elevated antiplatelet antibody (Hart et al). 1986; **154**:878-83
Epidemiology of hydatidiform mole during early gestation (Atrash et al). 1986; **154**:906-9
Factors influencing nonstress test results in multiple gestations (Patkos et al). 1986; **154**:1107-8
Fetal cystic hygroma colli: Antenatal diagnosis, significance, and management (Garden et al). 1986; **154**:221-5
Fetoplacental steroid metabolism in prolonged pregnancies (Reynolds et al). 1986; **154**:74-9
Folate deficiency presenting as pancytopenia in pregnancy (Solano Jr and Councell). 1986; **154**:1117-8
Gaucher's disease in pregnancy associated with portal hypertension (Mazor et al). 1986; **154**:1119-20
Goiter in pregnancy (Hegedüs et al) (Letter); (Long et al) (Reply). 1986; **154**:1164
Heat flux and oxygen consumption of the pregnant uterus (Rudelstorfer et al). 1986; **154**:462-70
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
Human chorionic gonadotropin in early normal and pathologic pregnancy (Steier et al). 1986; **154**:1091-4
Human platelet α-adrenergic receptors and responses during pregnancy: No change except that with differing hematocrit (Roberts et al). 1986; **154**:206-10
Hypertensive diseases of pregnancy and parity (Gleicher et al). 1986; **154**:1044-9
Immunoglobulin G subclasses and isoimmunized pregnancy outcome (Taslimi et al). 1986; **154**:1327-32
Incorporation of labeled ribonucleic acid precursors into maternal and fetal rat tissues during pregnancy (Dorko and Hayashi). 1986; **154**:801-5
Infective endocarditis in obstetric and gynecologic practice (Seaworth and Durack). 1986; **154**:180-8
Interrelationship between amniotic fluid C-peptide and catecholamines in the last trimester of diabetic pregnancy (Pschera et al). 1986; **154**:48-52
Kell sensitization in pregnancy (Caine and Mueller-Heubach). 1986; **154**:85-90
Leg static pressure values in pregnant women with iatrogenic pulmonary edema (Goodlin). 1986; **154**:634-5
Longitudinal study of platelet indices during normal pregnancy (Tygart et al). 1986; **154**:883-7
Lupus anticoagulant and pregnancy (Spitz et al) (Letter). 1986; **154**:1169
Management of postdate pregnancy (Lagrew and Freeman). 1986; **154**:8-13 (Clin. Opinion)
Maternal and fetal surveillance for older pregnant women (Schipul Jr et al) (Letter); (Kirz) (Reply). 1986; **154**: 967-8
Maternal ovine placental vascular responses to adenosine (Landauer et al). 1986; **154**:1152-5
Maternal-fetal ABO/Rh antigenic relationships and human fetal development (Hoff and Bixler). 1986; **154**:126-9
Meningoencephalitis caused by *Histoplasmc capsulatum* complicating pregnancy (McGregor et al). 1986; **154**:925-31
Multiple peripheral pulmonic stenosis in pregnancy (Landsberger and Grossman III). 1986; **154**:152-3
Ovarian pregnancy with a contralateral corpus luteum: Case report (Check and Chase). 1986; **154**:155-6
Perforated adenocarcinoma of the appendix during pregnancy (Donnenfeld et al). 1986; **154**:637-8
The perinatal and economic impact of prenatal care in a low-socioeconomic population (Moore et al). 1986; **154**:29-33
Physiologic changes in pregnant women and their fetuses during jet air travel (Huch et al). 1986; **154**:996-1000
Placental prostacyclin production in normal and toxemic pregnancies (Jeremy et al) (Letter); (Walsh) (Reply). 1986; **154**:212-4

Plasma catecholamine responses to physiologic stimuli in normal human pregnancy (Barron et al). 1986; **154**:80-4
Predictive value of fibronectin levels in normotensive gravid women destined to become preeclamptic (Lazarchick et al). 1986; **154**:1050-2
Prepregnancy weight, weight gain, and birth weight (Abrams and Laros Jr). 1986; **154**:503-9
Prevalence of hepatitis B surface antigen among women receiving prenatal care at the Palm Beach County Health Department (Malecki et al). 1986; **154**:625-6
The relation of angiotensin-converting enzyme to the pregnancy-induced hypertension–preeclampsia syndrome (Goldkrand and Fuentes). 1986; **154**:792-800
The relationship between abortion in the first pregnancy and development of pregnancy-induced hypertension in the subsequent pregnancy (Strickland et al). 1986; **154**:146-8
Relationship between log of the human chorionic gonadotropin concentration and time period in early pregnancy (Kadar) (Letter); (Pittaway) (Reply). 1986; **154**:692-4
Relaxin and the radiolucent fissure in the symphysis pubis during pregnancy: The gas phenomenon (Camiel). 1986; **154**:1104-5
Role of intravenous nitroglycerin in the treatment of severe pregnancy-induced hypertension complicated by pulmonary edema (Cotton et al). 1986; **154**:91-3
Serum fructosamine: A screening test for diabetes in pregnancy (Roberts and Baker). 1986; **154**:1027-30
Should a fifty-gram, one-hour plasma glucose screening test for gestational diabetes be administered in the fasting or fed state? (Coustan et al) 1986; **154**:1031-5
Sodium excretion in human pregnancy: A role for arginine vasopressin (Brown and Gallery). 1986; **154**:914-9
Squamous cells in the maternal pulmonary circulation (Clark et al). 1986; **154**:104-6
Tubal conservation in ectopic pregnancy: A study of 200 cases (Hallatt). 1986; **154**:1216-21
Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women (Sánchez et al). 1986; **154**:910-3
Ultrasound evaluation of amniotic fluid: Outcome of pregnancies with severe oligohydramnios (Bastide et al). 1986; **154**:895-900
Ultrasound evaluation of polyhydramnios and twin pregnancy (Hashimoto et al). 1986; **154**:1069-72
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9
Uterine activity during pregnancy in ambulatory patients: Comparison of singleton and twin gestations (Newman et al). 1986; **154**:530-1
Uterine artery Doppler velocimetry in pregnant women with hypertension (Fleischer et al). 1986; **154**:806-13
Uterine metabolism of the pregnant rabbit under chronic steady-state conditions (Johnson et al). 1986; **154**:1146-51

Premature labor
The effects of oral administration of progesterone for premature labor (Erny et al). 1986; **154**:525-9

Premature rupture of membranes; *see* **Membranes**

Prematurity; *see also* **Preterm labor and delivery**
Fetal heart rate monitoring and neonatal mortality in the very preterm infant (Braithwaite et al). 1986; **154**:250-4
The perinatal and economic impact of prenatal care in a low-socioeconomic population (Moore et al). 1986; **154**:29-33
Plasma growth hormone concentration in the chronically catheterized ovine fetus during spontaneous term delivery and premature delivery induced by continuous intravascular infusion of low doses of adrenocorticotropin or cortisol to the fetus (Lowe et al). 1986; **154**:420-3

Premenstrual syndrome
A double-blind placebo-controlled trial of progesterone vaginal suppositories in the treatment of premenstrual syndrome (Maddocks et al). 1986; **154**:573-81

Prenatal care
The perinatal and economic impact of prenatal care in a low-socioeconomic population (Moore et al). 1986; **154**:29-33
Prevalence of hepatitis B surface antigen among women receiving prenatal care at the Palm Beach County Health Department (Malecki et al). 1986; **154**:625-6

Presentation; *see* **Breech presentation**

Presidential address
Presidential address. 1986; **154**:699-708, 1173-80, 1285-90

Preterm labor and delivery
Adjunctive erythomycin treatment for idiopathic preterm labor: Results of a randomized, double-blinded, placebo-controlled trial (McGregor et al). 1986; **154**:98-103
Assessment of uterine activity in ambulatory patients at high risk of preterm labor and delivery (Katz et al). 1986; **154**:44-7
Detection of preterm labor by ambulatory monitoring of uterine activity for the management of oral tocolysis (Katz et al). 1986; **154**:1253-6
Effect of aminophylline on lung maturation in preterm rabbit fetuses (Cosmi et al). 1986; **154**:436-9
Failure to demostrate decreased β-adrenergic receptor concentration or decreased agonist efficacy in term or preterm human parturition (Dattel et al). 1986; **154**:450-6
Fetal heart rate monitoring and neonatal mortality in the very preterm infant (Braithwaite et al). 1986; **154**:250-4
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
Preterm labor: Its diagnosis and management (Gonik and Creasy). 1986; **154**:3-8 (Clin. Opinion)
A retrospective study on the effects of steroid administration and prolongation of the latent phase in patients with preterm premature rupture of the membranes (Arias et al). 1986; **154**:1059-63
Ultrasound differentiation of the competent from the incompetent cervix: Prevention of preterm delivery (Michaels et al). 1986; **154**:537-46

Progesterone; *see also* **Progestin**
A double-blind placebo-controlled trial of progesterone vaginal suppositories in the treatment of premenstrual syndrome (Maddocks et al). 1986; **154**:573-81
The effect of dehydroepiandrosterone sulfate on de novo and low-density lipoprotein–stimulated progesterone secretion by human choriocarcinoma JEG-3 cells (Moise et al). 1986; **154**:1080-5
The effects of oral administration of progesterone for premature labor (Erny et al). 1986; **154**:525-9
Fibrocystic breast disease: Pathophysiology, pathomorphology, clinical picture, and management (Vorherr). 1986; **154**:161-79
Human ovarian oxytocin: Its source and relationship to steroid hormones (Dawood and Khan-Dawood). 1986; **154**:756-63

Moderate recreational running is associated with lowered salivary progesterone profiles in women (Ellison and Lager). 1986; **154**:1000-3

Progestin; *see also* **Progesterone**
Biochemical and histologic effects of sequential estrogen/progestin therapy on the endometrium of postmenopausal women (Gibbons et al). 1986; **154**:456-61
Histologic and hormonal documentation of the luteinized unruptured follicle syndrome (Schenken et al). 1986; **154**:839-47

Prolactin
Correlation of the ultrasonic appearance of the ovaries in polycystic ovarian disease and the clinical, hormonal, and laparoscopic findings (el Tabbakh et al). 1986; **154**: 892-5
Decreased fetal cord prolactin concentration in diabetic pregnancies (Saltzman et al). 1986; **154**:1035-8
Epithelial regulation of prolactin effect on amnionic permeability (Raabe and McCoshen). 1986; **154**:130-4
Influence of sequential doses of 5-hydroxytryptophan on prolactin release (Sueldo et al). 1986; **154**:424-7
Inhibition of human chorionic gonadotropin production by prolactin from term human trophoblast (Ho Yuen et al). 1986; **154**:336-40
Opioid regulation of pituitary gonadotropins and prolactin in women using oral contraceptives (Snowden et al). 1986; **154**:440-4
Pergolide and bromocriptine for the treatment of patients with hyperprolactinemia (Kletzky et al). 1096; **154**: 431-5

Prolonged pregnancy; *see* **Postmaturity**

Prostacyclin
Placental prostacyclin production in normal and toxemic pregnancies (Jeremy et al) (Letter); (Walsh) (Reply). 1986; **154**:212-4

Prostaglandin
Preinduction cervical ripening with sequential use of prostaglandin E_2 gel (Prins et al). 1986; **154**:1275-9
Prostaglandin secretion by adrenal tissue of human anencephalic fetuses (Carr et al). 1986; **154**:373-8
Prostaglandins and endometriosis (Sgarlata and Hertelendy) (Letter); (James) (Reply). 1986; **154**:964-5
Relationship of gonadotropin-releasing hormone, danazol, and prostaglandin blockade to ovarian enlargement and ascites formation of the ovarian hyperstimulation syndrome in the rabbit (Pride et al). 1986; **154**:1155-60

Prostanoid
Peritoneal fluid in patients with and without endometriosis: Prostanoids and macrophages and their effect on the spermatozoa penetration assay (Chacho et al). 1986; **154**:1290-9

Protease
Protease production by microorganisms associated with reproductive tract infection (McGregor et al). 1986; **154**: 109-14

Protein
Biochemical and physiologic characterization of follicle regulatory protein: A paracrine regulator of folliculogenesis (Ono et al). 1986; **154**:709-16
The effect of antenatal dexamethasone on maternal and fetal retinol-binding protein (Hustead and Zachman). 1986; **154**:203-5
Human fallopian tube contains placental protein 14 (Julkunen et al). 1986; **154**:1076-9
Serum C-reactive protein determination in acute pelvic inflammatory disease (Lehtinen et al). 1986; **154**:158-9
Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein (Mogensen et al) (Letter). 1986; **154**:1165-6

Pseudohermaphroditism
Male pseudohermaphroditism due to 17-ketoreductase deficiency: Report of a case without gynecomastia and without vaginal pouch (Caufriez). 1986; **154**:148-9

Publications
Summary of analysis of published articles. 1986; **154**:477-8 (Editorial)

Puerperal fever
Lactation suppression and puerperal fever (Almeida and Kitay). 1986; **154**:940-1

Pulmonary circulation
Squamous cells in the maternal pulmonary circulation (Clark et al). 1986; **154**:104-6

Pulmonary edema
Leg static pressure values in pregnant women with iatrogenic pulmonary edema (Goodlin). 1986; **154**:634-5
Role of intravenous nitroglycerin in the treatment of severe pregnancy-induced hypertension complicated by pulmonary edema (Cotton et al). 1986; **154**:91-3

Pulmonic stenosis
Multiple peripheral pulmonic stenosis in pregnancy (Landsberger and Grossman III). 1986; **154**:152-3

Purpura; *see* **Thrombocytopenia**

Q

Quality assurance
A large community hospital's experience with an obstetrics-gynecology risk management committee: Quality assurance (Der Yuen). 1986; **154**:1206-10

R

Radiation
An analysis of the effects of increasing doses of ionizing radiation to the exteriorized rat ovary on follicular development, atresia, and serum gonadotropin levels (Jarrell et al). 1986; **154**:306-9
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6

Rape
Reported sexual assault in Nashville–Davidson County, Tennessee, 1980 to 1982 (Cartwright et al). 1986; **154**:1064-8

Reconstruction
A comparison of three techniques for ovarian reconstruction (Oelsner et al). 1986; **154**:569-72

Red blood cell; *see* **Erythrocyte**

Reference material
Proper study and use of reference material (Hein) (Letter); (Gortmaker) (Reply). 1986; **154**:216-7

Relaxin
Partial purification of relaxin from human seminal plasma (Weiss et al). 1986; **154**:749-55
Relaxin and the radiolucent fissure in the symphysis pubis during pregnancy: The gas phenomenon (Camiel). 1986; **154**:1104-5

Renal failure; *see also* **Kidney**
Septic shock with renal failure after chorionic villus sampling (Barela et al). 1986; **154**:1100-2

Reproductive tract abnormality; *see* **Anomaly**

Reproductive tract infection; *see* **Infection**

Residency
Experience with flexibility in an academic residency program (Hendricks). 1986; **154**:780-5 (Symposium)
Flexibility in obstetric-gynecologic residencies: Why is it necessary? (Willson) 1096; **154**:777-8 (Symposium)
The Golden Thread (Malkasian Jr). 1986; **154**:1285-90 (Pres. address)
The need for flexibility in preparing clinician-scientists for academic careers (Jaffe). 1986; **154**:778-80 (Symposium)
Response on the need for flexibility in academic obstetric-gynecologic residencies (Merrill). 1986; **154**:785-8 (Symposium)
Response on the need for flexibility in academic obstetric-gynecologic residencies (Pitkin). 1986; **154**:788-90 (Symposium)

Respiratory distress syndrome
Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity (Kogon et al). 1986; **154**:226-30
Decreased fetal cord prolactin concentration in diabetic pregnancies (Saltzman et al). 1986; **154**:1035-8
Effect of acetone precipitation on the clinical prediction of respiratory distress syndrome when utilizing amniotic fluid lecithin/sphingomyelin ratios (Hobson et al). 1986; **154**:1023-6
The effect of antenatal dexamethasone administration on the prevention of respiratory distress syndrome in preterm gestations with premature rupture of membranes (Morales et al). 1986; **154**:591-5
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74

Respiratory function
Cardiorespiratory fitness evaluation in climacteric women: Comparison of two methods (Notelovitz et al). 1986; **154**:1009-13

Retinol
The effect of antenatal dexamethasone on maternal and fetal retinol-binding protein (Hustead and Zachman). 1986; **154**:203-5

Retropubic cystourethropexy
Modified retropubic cystourethropexy (Goodno Jr and Powers). 1986; **154**:1211-5

Rh isoimmunization
Another view of controversy about Rh prophylaxis (Stephens) (Letter). 1986; **154**:968-9
Fetal microcirculation of abnormal human placenta. II. Scanning electron microscopy of placental vascular casts from fetus with severe erythroblastosis fetalis (Lee and Yeh). 1986; **154**:1139-46
Immunoglobulin G subclasses and isoimmunized pregnancy outcome (Taslimi et al). 1986; **154**:1327-32
Intravascular transfusion in utero: The percutaneous approach (Berkowitz et al). 1986; **154**:622-3
Kell sensitization in pregnancy (Caine and Mueller-Heubach). 1096; **154**:85-90
Maternal-fetal ABO/Rh antigenic relationships and human fetal development (Hoff and Bixler). 1986; **154**:126-9
Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization (Seeds and Bowes Jr). 1986; **154**:1105-7
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9

Ribonucleic acid
Incorporation of labeled ribonucleic acid precursors into maternal and fetal rat tissues during pregnancy (Dorko and Hayashi). 1986; **154**:801-5

Risk
Assessment of uterine activity in ambulatory patients at high risk of preterm labor and delivery (Katz et al). 1986; **154**:44-7
Has use of cesarean section reduced the risks of delivery in the preterm breech presentation? (Bodmer et al). 1986; **154**:244-50
Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study (Herbst et al). 1986; **154**:814-22
Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients (McGregor et al). 1986; **154**:955-60 (Symposium)
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74

Risk management
A large community hospital's experience with an obstetrics-gynecology risk management committee: Quality assurance (Der Yuen). 1986; **154**:1206-10

Ritodrine
Effect of ritodrine on uteroplacental blood flow and cardiac output distribution in unanesthetized pregnant guinea pigs (van de Walle and Martin Jr). 1986; **154**:189-94
Electrocardiographic changes associated with ritodrine-induced maternal tachycardia and hypokalemia (Hendricks et al). 1986; **154**:921-3
Myometrial desensitization to continuous but not to intermittent β-adrenergic agonist infusion in the sheep (Casper and Lye). 1986; **154**:301-5
Ritodrine-induced neutropenia (Wang-Cheng and Davidson). 1986; **154**:924-5

Robin anomalad
The prenatal diagnosis of Robin anomalad (Pilu et al). 1986; **154**:630-2

Rods
Is there a causal connection between motile curved rods, *Mobiluncus* species, and bleeding complications? (Larsson and Bergman). 1986; **154**:107-8

Rosette
Use of the erythrocyte rosette test to screen for excessive fetomaternal hemorrhage in Rh-negative women (Stedman et al). 1986; **154**:1363-9

Roster
Roster of American obstetric and gynecologic societies. 1986; **154**:218-9

Running; *see also* **Exercise**
Moderate recreational running is associated with lowered salivary progesterone profiles in women (Ellison and Lager). 1986; **154**:1000-3

S

Salpingitis; *see* **Infection; Pelvic inflammatory disease**

Semen
Partial purification of relaxin from human seminal plasma (Weiss et al). 1986; **154**:749-55

Sensitization; *see also* **Rh isoimmunization**
Kell sensitization in pregnancy (Caine and Mueller-Heubach). 1986; **154**:85-90

Septic shock
Septic shock with renal failure after chorionic villus sampling (Barela et al). 1986; **154**:1100-2

Serotonin
Influence of sequential doses of 5-hydroxytryptophan on prolactin release (Sueldo et al). 1986; **154**:424-7
Sex
Relationship of baseline fetal heart rate to gestational age and fetal sex (Druzin et al). 1986; **154**:1102-3
Sex hormone
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44
Sexual assault
Reported sexual assault in Nashville–Davidson County, Tennessee, 1980 to 1982 (Cartwright et al). 1986; **154**:1064-8
Shock
Septic shock with renal failure after chorionic villus sampling (Barela et al). 1986; **154**:1100-2
Shoulder dystocia
Another technique for resolution of shoulder dystocia (Carter) (Letter). 1986; **154**:964
Sickle cell anemia
Measurements of delta optical density at 450 nm in SS disease (Nelson) (Letter); (Lindsay and Lupo) (Reply). 1986; **154**:1166
Small bowel obstruction
Disagreement on use of water-soluble contrast material in small bowel obstruction (Ott et al) (Letter); (Robertson) (Reply). 1986; **154**:690-1
Smoking
Cigarette smoking and endometrial cancer (Baron) (Letter). 1986; **154**:965
Societies; *see also* **Papers; Transactions**
Roster of American obstetric and gynecologic societies. 1986; **154**:218-9
Society for Gynecologic Investigation
Papers of the Society for Gynecologic Investigation. 1986; **154**:362-475
Society of Obstetricians and Gynaecologists of Canada
Transactions of the forty-first annual meeting of the Society of Obstetricians and Gynaecologists of Canada. 1986; **154**:221-361
Socioeconomic level
The perinatal and economic impact of prenatal care in a low-socioeconomic population (Moore et al). 1986; **154**:29-33
Prevalence of hepatitis B surface antigen among women receiving prenatal care at the Palm Beach County Health Department (Malecki et al). 1986; **154**:625-6
Sodium
Sodium excretion in human pregnancy: A role for arginine vasopressin (Brown and Gallery). 1986; **154**:914-9
Sodium pentobarbital
Oxygen consumption in fetal lambs after maternal administration of sodium pentobarbital (Rurak and Taylor). 1986; **154**:674-8
Sonography; *see* **Ultrasound**
Spermatozoa
An evaluation of different media for the zona-free hamster egg penetration test (Mortimer). 1986; **154**: 351-4
Peritoneal fluid in patients with and without endometriosis: Prostanoids and macrophages and their effect on the spermatozoa penetration assay (Chacho et al). 1986; **154**:1290-9
Spontaneous abortion; *see* **Abortion**
Squamocolumnar junction
Behavior of the squamocolumnar junction during normal pregnancy (Ganesh et al) (Letter). 1986; **154**:689-90
Squamous cell
Squamous cells in the maternal pulmonary circulation (Clark et al). 1986; **154**:104-6
SS disease
Measurements of delta optical density at 450 nm in SS disease (Nelson) (Letter); (Lindsay and Lupo) (Reply). 1986; **154**:1166
Staging
Ovarian carcinoma of low malignant potential: Staging and treatment (Nation and Krepart). 1986; **154**:290-3
Staging laparotomy in early epithelial ovarian carcinoma (Helewa et al). 1986; **154**:282-6
Staphylococcal toxin
Toxic shock syndrome following carbon dioxide laser treatment of genital tract condyloma acuminatum (Bowen et al). 1986; **154**:145-6
Sterilization
Microsurgical reversal of sterilization: A six-year study (Spivak et al). 1986; **154**:355-61
Sterilization failures (Stock) (Letter); (Soderstrom) (Reply). 1986; **154**:970
Steroids
Fetoplacental steroid metabolism in prolonged pregnancies (Reynolds et al). 1986; **154**:74-9
Human ovarian oxytocin: Its source and relationship to steroid hormones (Dawood and Khan-Dawood). 1986; **154**:756-63
A retrospective study on the effects of steroid administration and prolongation of the latent phase in patients with preterm premature rupture of the membranes (Arias et al). 1986; **154**:1059-63
Streptococci
An obstetric approach to the prevention of early-onset group B β-hemolytic streptococcal sepsis (Minkoff and Mead). 1986; **154**:973-7
Stress incontinence
Modified retropubic cystourethropexy (Goodno Jr and Powers). 1986; **154**:1211-5
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64
Subcutaneous emphysema
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9
Sulfamethoxazole
Single-dose trimethoprim-sulfamethoxazole prophylaxis for cesarean section (Ganesh et al). 1986; **154**:1113-4
Superfusion
Corticotropin-releasing factor can stimulate gonadotropin secretion by human fetal pituitaries in superfusion (Blumenfeld et al). 1986; **154**:606-12
Surfactant; *see* **Respiratory distress syndrome**
Suture technique
A comparison of three techniques for ovarian reconstruction (Oelsner et al). 1986; **154**:569-72
Sympathectomy
Circulatory responses to hypovolemia in the pregnant and nonpregnant sheep after pharmacologic sympathectomy (Tabsh et al). 1986; **154**:411-9
β_2-Sympathomimetic drug
Effect of long-term administration of β_2-sympathomimetic drug in the diet-restricted pregnant rat model (Lipshitz et al). 1986; **154**:314-7

Symphysis pubis
Relaxin and the radiolucent fissure in the symphysis pubis during pregnancy: The gas phenomenon (Camiel). 1986; **154**:1104-5
Symposium
Symposium on cefotetan. 1986; **154**:945-63
Symposium on the need for flexibility in academic obstetric-gynecologic residencies: Why is it necessary? 1986; **154**:777-91
Syndrome
Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity (Kogon et al). 1986; **154**:231-4
Cushing's syndrome in pregnancy: A case report and literature review (Koerten et al). 1986; **154**:625-8
Severe hypoglycemia associated with the HELLP syndrome (Mabie and Sibai) (Letter); (Egley) (Reply). 1986; **154**: 211-2
A sonographic sign for fetal Down's syndrome (Defoort and Thiery) (Letter). 1986; **154**:1169-70
Subcutaneous emphysema, pneumomediastinum, and pneumothorax in labor and delivery (Reeder). 1986; **154**:487-9
Toxic shock syndrome following carbon dioxide laser treatment of genital tract condyloma acuminatum (Bowen et al). 1986; **154**:145-6
Use of the drop volume of amniotic fluid in estimating the risk for respiratory distress syndrome in the newborn infant (Åberg and Gislen). 1986; **154**:68-74

T

Tachycardia
Electrocardiographic changes associated with ritodrine-induced maternal tachycardia and hypokalemia (Hendricks et al). 1986; **154**:921-3
Teratology
The value of case reports in human teratology (Goldberg and Golbus). 1986; **154**:479-82 (Clin. Opinion)
Tertiary care center
Effects of maternal transport on admission patterns at a tertiary care center (Cowett et al). 1986; **154**:1098-100
Testosterone
Elevated concentrations of the β-subunit of human chorionic gonadotropin and testosterone in the amniotic fluid of gestations of diabetic mothers (Barbieri et al). 1986; **154**:1039-43
Testosterone levels and androgen-producing neoplasms (Meldrum) (Letter); (Friedman) (Reply). 1986; **154**: 965-6
Treatment of severe androgen excess due to ovarian hyperthecosis with a long-acting gonadotropin-releasing hormone agonist (Steingold et al). 1986; **154**:1241-8
Thrombocytopenia
Breast-feeding in thrombocytopenic neonates secondary to maternal autoimmune thrombocytopenic purpura (Meschengieser and Lazzari) (Letter); (Martin Jr) (Reply). 1986; **154**:1166-7
An epidemic of maternal thrombocytopenia associated with elevated antiplatelet antibody (Hart et al). 1986; **154**:878-83
Neonatal alloimmune thrombocytopenic purpura: A case report (Deaver et al). 1986; **154**:153-5
Percutaneous umbilical sampling in immune thrombocytopenic purpura (Sacks) (Letter); (Hobbins et al) (Reply). 1986; **154**:214-5
Thrombosis
Fetomaternal hemorrhage associated with umbilical vein thrombosis (Hoag). 1986; **154**:1271-4
Tinidazole
Are preoperative antibiotics helpful in abdominal hysterectomy? (Senior and Steigrad) 1986; **154**:1004-8
Tocolysis
Detection of preterm labor by ambulatory monitoring of uterine activity for the management of oral tocolysis (Katz et al). 1986; **154**:1253-6
The effects of oral administration of progesterone for premature labor (Erny et al). 1986; **154**:525-9
External cephalic version of the breech presentation under tocolysis (Morrison et al). 1986; **154**:900-3
Prophylactic tocolysis of twins (O'Leary). 1986; **154**:904-5
Ritodrine-induced neutropenia (Wang-Cheng and Davidson). 1986; **154**:924-5
Total abdominal hysterectomy; *see also* **Hysterectomy**
Total abdominal hysterectomy after radiation therapy for cervical cancer: Use of omental graft for fistula prevention (Petty et al). 1986; **154**:1222-6
Toxemia; *see also* **Eclampsia**
Expanded toxemia syndrome or gestosis (Goodlin). 1986; **154**:1227-33
Placental prostacyclin production in normal and toxemic pregnancies (Jeremy et al) (Letter); (Walsh) (Reply). 1986; **154**:212-4
Toxic shock syndrome
Toxic shock syndrome, contraceptive methods, and vaginitis (Lanes et al). 1986; **154**:989-91
Toxic shock syndrome following carbon dioxide laser treatment of genital tract condyloma acuminatum (Bowen et al). 1986; **154**:145-6
Training; *see* **Residency**
Transactions
Transactions of the fifty-third annual meeting of the Central Association of Obstetricians and Gynecologists. 1986; **154**:1285-1369
Transactions of the forty-first annual meeting of the Society of Obstetricians and Gynaecologists of Canada. 1986; **154**:221-361
Transactions of the fourth annual meeting of the American Gynecological and Obstetrical Society. 1986; **154**:699-854
Transactions of the fifty-second annual meeting of the Pacific Coast Obstetrical and Gynecological Society. 1986; **154**:1173-1284
Transfusions
Blood transfusions and Jehovah's Witnesses: Medical and legal issues in obstetrics and gynecology (Sacks and Koppes). 1986; **154**:483-6 (Clin. Opinion)
The effects of fetal exchange transfusion with a red blood cell substitute (Ambrose et al). 1986; **154**:667-74
Intravascular transfusion in utero: The percutaneous approach (Berkowitz et al). 1986; **154**:622-3
Transfusions of leukocyte-rich erythrocyte concentrates: A successful treatment in selected cases of habitual abortion (Unander and Lindholm). 1986; **154**:516-20
Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization (Seeds and Bowes Jr). 1986; **154**:1105-7
Transport
Effects of maternal transport on admission patterns at a tertiary care center (Cowett et al). 1986; **154**:1098-100
Trauma
Birth asphyxia, trauma, and mortality in twins: Has cesarean section improved outcome? (Bell et al). 1986; **154**:235-9

Travel
Physiologic changes in pregnant women and their fetuses during jet air travel (Huch et al). 1986; **154**:996-1000
Trimethoprim-sulfamethoxazole
Single-dose trimethoprim-sulfamethoxazole prophylaxis for cesarean section (Ganesh et al). 1986; **154**:1113-4
Trisomy
Hydrops fetalis and chromosomal trisomies (Landrum et al). 1986; **154**:1114-5
Maternal serum α-fetoprotein and fetal autosomal trisomies (Doran et al). 1986; **154**:277-81
Tritium
Incorporation of labeled ribonucleic acid precursors into maternal and fetal rat tissues during pregnancy (Dorko and Hayashi). 1986; **154**:801-5
Trophoblast
Inhibition of human chorionic gonadotropin production by prolactin from term human trophoblast (Ho Yuen et al). 1986; **154**:336-40
Tumor marker
CA 125 surveillance and second-look laparotomy in ovarian carcinoma (Atack et al). 1986; **154**:287-9
The tumor marker CA 125 is a common constituent of normal cervical mucus (de Bruijn et al). 1986; **154**:1088-91
Tumor markers in ovarian cancer: A comparison between immunosuppressive acidic protein and α_1-acid glycoprotein (Mogensen et al) (Letter). 1986; **154**:1165-6
Twins
Birth asphyxia, trauma, and mortality in twins: Has cesarean section improved outcome? (Bell et al). 1986; **154**:235-9
Cesarean delivery of the second twin after vaginal delivery of the first twin (Rattan et al). 1986; **154**:936-9
Factors influencing nonstress test results in multiple gestations (Patkos et al). 1986; **154**:1107-8
Prophylactic tocolysis of twins (O'Leary). 1986; **154**:904-5
Ultrasound evaluation of polyhydramnios and twin pregnancy (Hashimoto et al). 1986; **154**:1069-72
Uterine activity during pregnancy in ambulatory patients: Comparison of singleton and twin gestations (Newman et al). 1986; **154**:530-1
Two-dimensional echocardiography
Quantitative two-dimensional echocardiographic assessment of fetal cardiac growth (Shime et al). 1986; **154**:294-300
Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women (Sánchez et al). 1986; **154**:910-3

U

Ultrasound
Antenatal diagnosis of renal anomalies with ultrasound. IV. Bilateral multicystic kidney disease (D'Alton et al). 1986; **154**:532-7
Congenital heart disease and extracardiac anomalies: Associations and indications for fetal echocardiography (Copel et al). 1986; **154**:1121-32 (Curr. Dev.)
Correlation of the ultrasonic appearance of the ovaries in polycystic ovarian disease and the clinical, hormonal, and laparoscopic findings (el Tabbakh et al). 1986; **154**:892-5
Failure of nonstress test and Doppler-assessed umbilical arterial blood flow to detect imminent intrauterine death (Erskine et al). 1986; **154**:1109-10
Fetal cystic hygroma colli: Antenatal diagnosis, significance, and management (Garden et al). 1986; **154**:221-5
Magnetic resonance imaging and placenta previa (Power et al). 1986; **154**:565-9
A sonographic sign for fetal Down's syndrome (Defoort and Thiery) (Letter). 1986; **154**:1169-70
Ultrasonographic evidence of uterine malignancy in the postmenopausal uterus (Chambers and Unis). 1986; **154**:1194-9
Ultrasound differentiation of the competent from the incompetent cervix: Prevention of preterm delivery (Michaels et al). 1986; **154**:537-46
Ultrasound evaluation of amniotic fluid: Outcome of pregnancies with severe oligohydramnios (Bastide et al). 1986; **154**:895-900
Ultrasound evaluation of polyhydramnios and twin pregnancy (Hashimoto et al). 1986; **154**:1069-72
"Ultrasound rescue": A successful alternative form of oocyte recovery in patients with periovarian adhesions (Taylor et al). 1986; **154**:240-4
Ultrasound-guided fetal intravascular transfusion in severe rhesus immunization (Seeds and Bowes Jr). 1986; **154**:1105-7
Uterine artery Doppler velocimetry in pregnant women with hypertension (Fleischer et al). 1986; **154**:806-13
Umbilical artery
Blunted response of maternal ovine placental lactogen levels to arginine stimulation after single umbilical artery ligation in pregnant sheep (Newnham et al). 1986; **154**:663-6
The effect of maternal consumption of alcohol on human umbilical artery blood flow (Erskine and Ritchie). 1986; **154**:318-21
Failure of nonstress test and Doppler-assessed umbilical arterial blood flow to detect imminent intrauterine death (Erskine et al). 1986; **154**:1109-10
Umbilical cord
Decreased fetal cord prolactin concentration in diabetic pregnancies (Saltzman et al). 1986; **154**:1035-8
The length of the human umbilical cord in vertex and breech presentations (Soernes and Bakke). 1986; **154**:1086-7
Percutaneous umbilical sampling in immune thrombocytopenic purpura (Sacks) (Letter); (Hobbins et al) (Reply). 1986; **154**:214-5
Umbilical vein
Fetomaternal hemorrhage associated with umbilical vein thrombosis (Hoag). 1986; **154**:1271-4
Urinary incontinence
Modified retropubic cystourethropexy (Goodno Jr and Powers). 1986; **154**:1211-5
The role of biofeedback in Kegel exercise training for stress urinary incontinence (Burgio et al). 1986; **154**:58-64
Uterine blood flow
The effect of a calcium channel blocker (nifedipine) on uterine blood flow in the pregnant goat (Veille et al). 1986; **154**:1160-3
Effect of ritodrine on uteroplacental blood flow and cardiac output distribution in unanesthetized pregnant guinea pigs (van de Walle and Martin Jr). 1986; **154**:189-94
Effects of reduced uterine blood flow on accelerations and decelerations in heart rate of fetal sheep (Bocking et al). 1986; **154**:329-35
Effects of reduced uterine blood flow on electrocortical activity, breathing, and skeletal muscle activity in fetal sheep (Bocking and Harding). 1986; **154**:655-62
Extracorporeal perfusion of the human uterus (Bulletti et al). 1986; **154**:683-8

Temporal and receptor correlates of the estrogen response in sheep (Greiss Jr et al). 1986; **154**:831-8
Uterine artery Doppler velocimetry in pregnant women with hypertension (Fleischer et al). 1986; **154**:806-13

Uterus
Assessment of uterine activity in ambulatory patients at high risk of preterm labor and delivery (Katz et al). 1986; **154**:44-7
In defense of the vertical uterine incision (Goodlin) (Letter); (Jovanovic) (Reply). 1986; **154**:956-7
Effect of hexoprenaline on uteroplacental blood flow in the pregnant rat (Lipshitz et al). 1985; **154**:310-4
Effects of reduced uterine blood flow on electrocortical activity, breathing, and skeletal muscle activity in fetal sheep (Bocking and Harding). 1986; **154**:655-62
Endometriosis in association with uterine anomaly (Sanfilippo et al). 1986; **154**:39-43
Extracorporeal perfusion of the human uterus (Bulletti et al). 1986; **154**:683-8
Failure to demostrate decreased β-adrenergic receptor concentration or decreased agonist efficacy in term or preterm human parturition (Dattel et al). 1986; **154**:450-6
Finger extension of transverse uterine incision (Gerace) (Letter); (Jovanovic) (Reply). 1986; **154**:1168-9
Heat flux and oxygen consumption of the pregnant uterus (Rudelstorfer et al). 1986; **154**:462-70
Myometrial desensitization to continuous but not to intermittent β-adrenergic agonist infusion in the sheep (Casper and Lye). 1986; **154**:301-5
Pharmacologic levels of nitrendipine do not affect actin-myosin interaction in the human uterus and placenta (Sakamoto and Huszar). 1986; **154**:402-7
Temporal and receptor correlates of the estrogen response in sheep (Greiss Jr et al). 1986; **154**:831-8
Ultrasonographic evidence of uterine malignancy in the postmenopausal uterus (Chambers and Unis). 1986; **154**:1194-9
Uterine activity during pregnancy in ambulatory patients: Comparison of singleton and twin gestations (Newman et al). 1986; **154**:530-1
Uterine metabolism of the pregnant rabbit under chronic steady-state conditions (Johnson et al). 1986; **154**:1146-51

Utilization review
Obstetric hospital stays by diagnosis related groups: A community-based analysis (Lagoe). 1986; **154**:873-8

V

Vagina
Amniostat-FLM: An initial clinical trial with both vaginal pool and amniocentesis samples (Benoit et al). 1986; **154**:65-8
Vaginal colonization with *Escherichia coli* in healthy women (Chow et al). 1986; **154**:120-6

Vaginal suppository
A double-blind placebo-controlled trial of progesterone vaginal suppositories in the treatment of premenstrual syndrome (Maddocks et al). 1986; **154**:573-81

Vaginal vault suspension
Postoperative intussusception after vaginal vault suspension (Hunter et al). 1986; **154**:633-4

Vaginitis
Toxic shock syndrome, contraceptive methods, and vaginitis (Lanes et al). 1986; **154**:989-91

Varicella
Excretion of varicella–herpes zoster virus in breast milk (Frederick et al). 1986; **154**:1116-7

Vasopressin
Sodium excretion in human pregnancy: A role for arginine vasopressin (Brown and Gallery). 1986; **154**:914-9

Velocimetry
Uterine artery Doppler velocimetry in pregnant women with hypertension (Fleischer et al). 1986; **154**:806-13

Version
External cephalic version of the breech presentation under tocolysis (Morrison et al). 1986; **154**:900-3

Vertex presentation
The length of the human umbilical cord in vertex and breech presentations (Soernes and Bakke). 1986; **154**:1086-7

Vertical uterine incision
In defense of the vertical uterine incision (Goodlin) (Letter); (Jovanovic) (Reply). 1986; **154**:966-7

Vibratory acoustic stimulation
Fetal response to vibratory acoustic stimulation in periods of low heart rate reactivity and low activity (Ohel et al). 1986; **154**:619-21

Virus
Excretion of varicella–herpes zoster virus in breast milk (Frederick et al). 1986; **154**:1116-7
Herpes simplex virus testing of an obstetric population with an antigen enzyme-linked immunosorbent assay (Warford et al). 1986; **154**:21-8
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15

Vitamin A
The effect of antenatal dexamethasone on maternal and fetal retinol-binding protein (Hustead and Zachman). 1986; **154**:203-5

Vitamin E
Influence of breast-feeding on the restoration of the low serum concentration of vitamin E and β-carotene in the newborn infant (Ostrea Jr et al). 1986; **154**:1014-7

Vulva
Focal vulvitis: A characteristic syndrome and cause of dyspareunia: Features, natural history, and management (Peckham et al). 1986; **154**:855-64
The role of lymphangiography in vulvar carcinoma (Weiner et al). 1986; **154**:1073-5

W

Wart virus
Quantitative assessment of Langerhans' cells in human cervical intraepithelial neoplasia and wart virus infection (McArdle and Muller). 1986; **154**:509-15

Water-soluble contrast material
Disagreement on use of water-soluble contrast material in small bowel obstruction (Ott et al) (Letter); (Robertson) (Reply). 1986; **154**:690-1

Weight; *see also* **Birth weight**

Weight
Effect of weight loss and antiandrogenic therapy on sex hormone blood levels and insulin resistance in obese patients with polycystic ovaries (Pasquali et al). 1986; **154**:139-44

Prepregnancy weight, weight gain, and birth weight (Abrams and Laros Jr). 1986; **154**:503-9

Y

Y chromosome
Use of two different deoxyribonucleic acid probes to detect Y chromosome deoxyribonucleic acid in subjects with normal and altered Y chromosomes (McDonough et al). 1986; **154**:737-48

Z

Zona-free hamster egg penetration test
An evaluation of different media for the zona-free hamster egg penetration test (Mortimer). 1986; **154**:351-4

Zuclomiphene citrate
The effects of enclomiphene and zuclomiphene citrates on mouse embryos fertilized in vitro and in vivo (Schmidt et al). 1986; **154**:727-36

DIRECTOR OF PRENATAL DIAGNOSIS
INSTITUTE FOR MOLECULAR GENETICS
BAYLOR COLLEGE OF MEDICINE

The Institute for Molecular Genetics at Baylor College of Medicine in Houston, Texas is seeking a Director for the R.J. Kleberg Center for Prenatal Diagnosis. Qualifications include certification in OB/GYN and the American Board of Human Genetics or the equivalent. Applicants should send a current curriculum vitae and list of references to: Dr. C. Thomas Caskey, Professor and Director, Institute for Molecular Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, Texas 77030.

FELLOWSHIP IN MATERNAL AND FETAL MEDICINE

The established accredited fellowship in maternal and fetal medicine of the Bowman Gray School of Medicine is seeking applicants for a position as first year fellow beginning July 1987. The fellowship is a two year clinical and research oriented program. The clinical services are centered at the 700 bed Forsyth Memorial Hospital with over 4,500 deliveries annually and an active combined Perinatal Service. Research opportunities include active programs in fetal sheep, primate, hormone receptor and ultrasound investigation. Both clinical and laboratory research are encouraged and supported by the Bowman Gray School of Medicine and fellows' major time commitment is to career development and research. Applicants must have completed an approved residency in Obstetrics and Gynecology by July 1986.

For further information please write:

Paul J. Meis, M.D.
Professor and Head
Section on Maternal-Fetal Medicine
or
Frank C. Greiss, Jr., M.D.
Professor and Chairman

EOE-AA

Medical Genetics Medical Staff Fellowship
The Interinstitute Medical Genetics Program
National Institutes of Health

The Interinstitute Medical Genetics Program of the National Institutes of Health offers fellowships providing a comprehensive clinical and laboratory experience in medical genetics. The fellowships begin July, 1988 and are offered for two years. Applications are invited from individuals of the highest caliber with the M.D. or M.D.-Ph.D. degree who have completed at least two years of postgraduate clinical training and who are seriously interested in pursuing careers in academic medicine and research. Clinical training involves inpatient and outpatient services at the NIH 480-bed research and teaching hospital, which, with collaborating medical facilities, provides a broad exposure to clinical genetics, diagnosis and counseling, cytogenetics, biochemical and cancer genetics, screening techniques and prenatal diagnosis. Exceptional research opportunities exist in the institutes' multiple laboratories. The program staff includes scientists and physicians of international stature.

As a medical staff fellow you will receive an initial salary of $30,000, with increments of $2,000 per year up to a maximum of $34,000. Moving, travel expenses and Federal health care benefits are available. Interested candidates should submit their *curriculum vitae* to or request further information from:

The Fellowship Program
Building 10, Room 2N-220
National Institutes of Health
Public Health Service
Bethesda, MD 20892

Telephone: (301) 496-2427

Deadline for applications is November 15, 1986.

NIH is an Equal Opportunity Employer

OBSTETRICIAN/ GYNECOLOGIST

with interests including high risk obstetrics and pelvic surgery to join five physician department in multispecialty clinic in Madison, Wisconsin. Excellent environment, Level 3 hospital, neonatologists, and supporting staff available. Competitive fringe benefits and salary. Send curriculum vitae to:

Louis C. Bernhardt, M.D.
Dean Medical Center
1313 Fish Hatchery Road
Madison, WI 53715

OBSTETRICIAN-GYNECOLOGIST

Board certified or eligible to join an existing Obstetrician-Gynecologist in an expanding multi-specialty practice in Northern Wisconsin. The staff also includes five Family Practitioners, four Internists, one General Surgeon, one Radiologist, and two Physician Assistants. Clinic adjoins a JCAH accredited hospital. New 2nd Edition!

HUMAN EMBRYOLOGY

By F. Beck, D.Sc., M.D., Ch.B.; D.B. Moffat, M.D., F.R.C.S.; and D.P. Davies, B.Sc., M.B., D.C.H., D.Obst., F.R.C.P.
This new edition has been completely updated, with emphasis on clinical details of inherited anomalies. Chapters on developmental anatomy give you a clear account of the formation of all the body systems, set against a background of general reproductive physiology and anatomy. In addition, the sections on growth and development and their disorders have been greatly expanded—with emphasis on their clinical importance.
1986. 383 pages, 204 illustrations. (B-0557-1) $18.95

New!

MEDICAL GYNAECOLOGY

Edited by M.C. Macnaughton, M.D., F.R.C.O.G., F.R.C.P.(Glas.), F.R.S.E.; with 10 contributors
This book underlines the breadth of important gynecologic issues—research into endocrine, immunological and psychological issues in the health of women, matched only by the concern of your patients themselves. If you pick it up, you won't put it down!
Contents include: Sexual dysfunction; The recognition and management of the fluid retention and premenstrual syndromes; Genetic counselling; Pregnancy counselling; Infertility; Artificial insemination by donor (AID) and artificial insemination by husband (AIH); Genitourinary medicine; Family planning; and more
1985. 282 pages, illustrated. (B-3194-7) $32.95

Contemporary Issues in Fetal and Neonatal Medicine Series: PERINATAL BRAIN DAMAGE

By Karen E. Pape, M.D. and Jonathan S. Wigglesworth, M.D., F.R.C.Path.
Here you'll find all that's important in understanding and managing perinatal brain damage. Expert contributors provide you with a practical discussion of the causes and treatment of perinatal brain damage.
Chapters Include: CT—the State of the Art; Ultrasound—the State of the Art; Magnetic Resonance Imaging and New Imaging Techniques; Birth Asphyxia—Scientific Studies and Clinical Problems; Intraventricular Hemorrhage; Cerebral Blood Flow Management; Diagnosis and management of hydrocephalus; Follow-up of neonatal brain injured children
March, 1986. Approx. 250 pages. (A-3787-2) About $25.00

New!

BREAST CANCER: Treatment and Progress

Edited by B.A. Stoll, F.R.C.R., F.F.R.
This book examines, in a critical and realistic manner, the final goals in any treatment of breast cancer. It looks at the chances of achieving these goals, the price to be paid by your patient and the prospects of more effective treatment likely to become available in the foreseeable future. Instead of being concerned with comparisons of different types of therapy in large groups of patients, this book places the emphasis firmly on the individual patient.
June, 1986. Approx. 400 pages, 60 illustrations. (B-4921-8) About $50.50

ORTHO-NOVUM 1/77

TRADEMARK

Tablets

(norethindrone/ethinyl estradiol)

Enhanced patient compliance

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

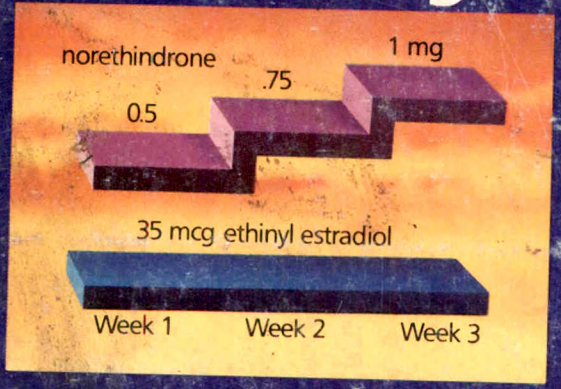
Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY. BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert).** **DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Revised 12/84

ORTHO-PHARMACEUTICAL CORPORATION
Raritan, New Jersey 08869



OJ-783

ORTHO

#1 for new start pat

What to look for in a phasic†...Reason 1

Unique, week-by-week design

- No hormonal drop-off
- Hormonal doses balanced for endometrial support

7 7 7

Designed for performance

21- and 28-day regimens

ORTHO-NOVUM 7/7/7

TRADEMARK

(norethindrone/ethinyl estradiol)

Tablets

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.
Please see complete Prescribing Information, a summary of which appears on the preceding page.
